SUPPLEMENT TO "THE ELECTRICIAN," MAY 6, 1887.

THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

VOLUME XVIII.

FROM NOVEMBER 12, 1886, TO MAY 6, 1887.

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.

LONDON:
Printed and Published for the Proprietors by GEORGE TUCKER, at "THE ELECTRICIAN" Offices, 1, Salisbury-court, Fleet-street, E.C.

1887.

INDEX TO VOL. XVIII.

A

Abercromby, R., Sunrise Shadows in Ceylon, 43.
Accumulators (*see* BATTERIES, SECONDARY).
Acheson's Duplex Wire, 330.
Alloys, Conductivity of Some, by C. L. Weber, 109.
Allpress, V. S., Primary Batteries for Lighting, 33.
Alternating Currents for Determining the Conductivity of Electrolytes, by T. C. Fitzpatrick, 400.
Alternating Currents for Measuring Liquid Resistances, by Bouty and Foussereau, 105.
Aluminium, Electro-deposition of, 305.
Aluminium, Rubies obtained from the Smelting of, 459.
American Bell Telephone Company, Apparatus made by, 233.
Ammeters and Switches, the E.P.S., 467.
Anderson, Sir J., Cables and War, 191.
Anglo-American Brush Company *v.* Crompton, 90.
Arnoux, R., Dynamo Design, 110.
Arrhenius, S., Action of Electrolysis on an Electrolyte, 105
Arrhenius, S., Conductivity of Aqueous Acid Solutions, 217.
Atlantic Cables, Proposed (Leading Article), 59.
Ayrton and Perry, Magnetic Resistance, 442.
Ayrton and Perry, Relation of Capacity to Thickness of Dielectric, 442.

B

Barrett, J., his Method of duplexing Telephone Circuits, 18.
Batteries, Primary:—
Bidwell's Lead Cell, 132.
for Lighting, by V. S. Allpress, 33.
Method of Determining Resistance of, 426.
Upward's, 348.
by S. F. Walker, 243, 264.
Walker's Cell, 213.
Batteries, Secondary:—
Brush and Faure's Patent in the United States, 145.
for Electric Lighting, by D. G. FitzGerald, 397, 414, 442, 457.
Kent's Automatic Switch for, 479.
Swinburne's Experiments on, 153, 173.
Union Company's Cell, 190.
Bells, Electric, Moseley's Improvements, 85, 152.
Bentley and Knight's Electric Railway, 240.
Bernstein's System of Lighting, Improvements in, 202.
Bidwell, S., Diathermancy and Electrolytic Conductivity, 35.
Bidwell, S., Resistance of Suspended Wires, 441.
Bidwell, S., Self-induction, 441.
Bidwell's Lead Battery, 132.
Bills Proposed in Session, 1887, 89.
Bolton, Sir F., Death of, 190, 332.
Books, Reviews of (*see* REVIEWS).
Bosanquet, R. H. M., Determining Coefficients of Mutual Induction, 381.
Bosanquet, R. H. M., Electro-magnets—Tension of Lines of Force, 83.
Bosanquet, R. H. M., Permanent Magnets—Magnetic Decay, 145.
Bosanquet, R. H. M., Magnetisation, Sequences of Reversals, 551.
Bouty, E., Conductivity of Potassic Chloride, 311.
Bouty, E., Conductivity of Weak Salt Solutions, 62, 81.
Bouty, E., Electrolytic Conductivity, 34, 61.
Bouty, E., Mechanical and Thermal Effects of Electrolysis, 105.
Bouty and Foussereau, Alternating Currents for Measuring Liquid Resistances, 105.
Boys, C. V., Fibres, 489.
Bright, Sir C., Presidential Address to S. T. E. and E., 219, 245.
Brighton Electric Railway, 260, 269.
British Association (*see* SOCIETIES' MEETINGS).
Bruger, T., Solenoids and Iron Cores, 147.
Brush Company's Portable Electric Light Apparatus, 371.
Brush and Victoria Dynamos, 198, 199.
Burglar Alarm, Taussig's, 441.
Business Notices, 24, 92, 204 248, 406, 428, 450 (*see also* CITY NOTES).

C

Cables:—
for Alternating Currents, 543.
to Australia (criticisms by *Imperial Federation*), 374.
or Cruisers, 79, 191.
and The Empire (Leading Article), 544.
Faults in, by A. E. Kennelly, 468, 486, 506, 530.
France and Ocean Cables, 328, 334.
to New Zealand, 39, 57.
proposed Atlantic (Leading Article), 59.
and Submarine Telegraphy, 456, 482, 497, 520.
Callow *v.* Young, 68.
Calorific Equivalents, Professor Thomson's, criticised by D. G. FitzGerald, 457.
Calorific Values and E.M.F.'s, by D. G. FitzGerald, 498.
Capacity, its Relation to Thickness of Dielectric, by Professors Ayrton and Perry, 442.
Capital and Dividend, Reduction of (Leading Article), 80.
Cauchy's Theory of Light, by J. Walker, 132.
Central Institution and Finsbury College (Leading Article), 480.
Central Stations, Hourly Variations in Current from, 123.
Central Stations, Plans for Installing, by A. F. Upton, 427.
Chamberlain-Hookham Dynamo, 304.
Champain, Col. Sir J. B., Death of, 283, 332.
Chauvin, M., Magnetic Rotary Power of Crystals, 310.
Cherrill, N. K., Varnishing Incandescent Lamps, 484.
City Notes, 318, 340, 362, 384, 406, 428, 450, 472, 490, 512, 534, 555, 574.
Clausius, —., Relation of Electricity and Heat, 110.
Clayden, A. W., Internal Capacity of Thermometers, 43.
Cocks *v.* Great Western Railway, 44, 67, 449, 500.
Colonial Exhibition, Tests of Engines at, 52.
Commutator for Converting Continuous into Alternating Currents, Pfaunkuche's, 523.

COMPANIES' MEETINGS, REPORTS, &c.:—
Anglo-American Brush, 339, 359.
Anglo-American Telegraph, 266, 315.
Blackpool Tramway, 68, 92.
Brazilian Submarine, 574.
Cuba Submarine, 274, 295.
Direct Spanish Telegraph, 449, 470.
Direct United States Cable, 226, 271.
Eastern Extension Telegraph, 534, 552.
Eastern Telegraph, 226, 247, 270.
Electrical Power Storage, 450, 470.
Equitable Telephone, 555.
German Union, 428, 449.
Great Northern of Copenhagen, 573.
Gülcher Electric Light, 156.
India Rubber, &c., 274, 318, 358.
Indo-European Telegraph, 534, 551.
Maxim-Weston, 404.
Montevidean Telegraph, 449.
New Telephone, 179, 274.
Oriental Telephone, 489, 554.
Pilsen-Joel, 46, 180.
Reuter's Telegram, 534, 554.
River Plate Telephone, 90, 136, 532.
Simplex Syndicate, 179.
Submarine Cables Trust, 574.
Submarine Telegraph, 338.
Swan United, 340, 360.
Telegraph Construction, 383.
Telephone Company of Egypt, 383.

COMPANIES' MEETINGS (*continued*):
Telephone of Ireland, 490, 533.
United River Plate Telephone, 532.
West Coast of America Telegraph, 455, 573.
West India Telegraph, 24, 44.
Western and Brazilian, 384, 403.
Western Counties Telephone, 512.

Companies Formed during 1886, 201.
Companies, New, 114, 158, 472, 490, 555.
Concert given by Eastern Telegraph Company's Staff, 178.
Conductivity of Alloys, by C. L. Weber, 109.
Conductivity of Aqueous Acid Solutions, by S. Arrhenius, 217.
Conductivity of Dilute Solutions, by F. Kohlrausch, 16.
Conductivity of Electrolytes, Alternate Currents for Determining, by T. C. Fitzpatrick, 400.
Conductivity, Electrolytic, by S. Bidwell, 35.
Conductivity, Electrolytic, by Professor Bouty, 34, 61.
Conductivity of Potassic Chloride, by E. Bouty, 311.
Conductivity of Weak Salt Solutions, by E. Bouty, 62, 81.
Conduction, Electric, by Dr. Hopkinson, 17.
Conductors, Compound, Self-Induction of, by Lord Rayleigh, 170, 222, 240.
Contemporary Progress, by G. W. von Tunzelmann:—
Bouty, Conductivity of Potassic Chloride, 311.
Chauvin, Magnetic Rotary Power of Crystals, 310.
Cornu, The form of the Wave Surface of Light in an Isotropic Medium in a Magnetic Field, also, Existence of a Special Double Refraction in a Direction Normal to the Lines of Force, 107.
Cornu and Potier, Verification of Verdet's Law, 107.
Streintz and Aulinger, Polarisation of Lead, 309.
Weber, C. L., Conductivity of some Alloys, 109.
Wild, Terrestrial Magnetic Disturbances and Solar Phenomena, 310.
Copper Disc Galvanometer for Alternate Currents, 561.
Copper Wires, Resistance of Suspended, by S. Bidwell, 441.

Correspondence:—

Accumulators, *see* BATTERIES, SECONDARY.
Almack, E., Electioneering and Scientific Societies, 103.
Alternating Currents, Novel Phenomena, 546.
Aluminium, How to Solder it, 285.
Anode and Cathode, 462.
Armature Cores, Stationary, 307.
Armature Winding, 100.
Babbage's Notation, 147.
Batteries, Primary:—
and Electric Lighting, 285.
Pollack's Cell, 327, 351.
Batteries, Secondary:—
Automatic Switches for, 502, 523.
Gudot's Cell, 14, 38.
Union Company's Cell, 213, 239, 261, 417, 439.
Mercury Contacts and Celluloid for, 461, 482, 501.
Theory of 481, 501, 521, 545.
Bernstein, A., Secondary Generators, 60.
Blathy, O. T., Heating of Cores, 327.
Bosanquet, R. H. M., Characteristics of Dynamos and Notation, 37, 78, 100, 125.
Bray Electric Tramway, 462, 502.
Butler, H. W. Secondary Batteries, 417, 461.
Calories and Volts, 546.
Carbon Filaments, 239.
Carbon, Retort, 165.
Cardew, P., Dynamo Testing, 101.
Chambers, R., Retort Carbon, 165.
Connolly, T., Electric Lighting in Mines, 285.
Cook, D., Babbage's Notation, 147.

THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

No. 1.—Vol. XVIII. FRIDAY, NOVEMBER 12, 1886. Price 4d.

NOTES.

The Bath-Bristol Telephone Line.—This line was opened for public use on Monday last.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended 5th inst. amounted to £3,563.

The Electric Railways of the World.—It is stated that the number of electrical railways and tramways now in existence approaches the respectable total of eighty.

Compass Errors.—We are informed that the wreck of the British steamship "Juliet," on the American coast, was due to the errors of her compass, induced by the cargo of steel rails which she carried.

Royal College of Science, Dublin.—On Friday next, Prof. W. F. Barrett commences a course of six evening lectures to working men at the above college, on "The Industrial Application of Electricity."

Cutting a Telegraph Wire.—At the Worship-street Police Court, a man named Albert Sanders was sent to gaol for three months without the option of a fine, for maliciously cutting a wire belonging to the Exchange Telegraph Company.

The Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ended Nov. 5 were £2,924, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

A Telegraphic Play.—At the Lyceum Theatre, New York, a play is now running, called "The Main Line." In one of the scenes the interior of a large telegraph office is presented on the stage, and messages are received and transmitted on Morse sounders.

The National Telephone Company.—The jurors have awarded the National Telephone Company a gold medal at the Edinburgh International Exhibition. In all probability this exhibit formed one of the most complete displays of telephonic appliances ever brought together.

Dynamo Electric Machinery.—The important paper on "Dynamo Electric Machinery," by Drs. J. and E. Hopkinson, which was read before the Royal Society on 6th May, has just been published in *Philosophical Transactions*, and we hope to reproduce it in our pages at an early date.

Telephonic Extensions in Spain.—The *Imparcial* says that telephonic communication is about to be established between the port of Motril and Salobrina, in the province of Granada, and that another line from Cangas de Tineo to Grado, in Asturias, is almost finished, and will shortly be opened for traffic.

Tenders Wanted.—Tenders for the supply of wire and telegraph instruments are asked for by the Midland Railway Company. Patterns may be inspected at the General Stores Department, Derby, and tenders will be received up to 9 a.m. on the 17th inst., addressed to the Secretary, General Stores Committee, Midland Railway, Derby.

Price of Gas in the United States.—It will be of some interest to electric lighting engineers in this country to learn that, according to a statement made at the recent meeting of the American Gas-Light Association, the lowest price charged for gas by any company in the States is 90 cents per thousand feet, and the highest $6 per thousand; the average price being $1.74 per thousand.

Communication Wanted.—At a meeting of the Brandon Local Board last week, on the suggestion of one of its members, the clerk was instructed to draw up a memorial for presentation to the Post Office authorities in support of the inhabitants of the Dearness Valley, who are just now endeavouring to get telegraphic and telephonic communication established between them and the outside world.

Spanish Tenders for Telegraph Wire.—The Madrid papers contain a notification to the effect that tenders will be received on the 6th December next at the Central Offices of the Post and Telegraph Department, Madrid, for the supply of 60 tons of galvanised iron wire, of four millimetres in diameter, required for the construction of a line from Lérida to Viella. The prices and conditions are on view at the offices in Madrid.

Electric Light at a Leeds Music Hall.—Messrs. Walsh and Co., of Leeds, have recently fitted 30 Swan 20 candle-power lamps in the lounge of the Prince's Palace Music Hall in that town. The lamps are supplied with current from a set of E.P.S. accumulators, and the latter charged over a circuit a quarter of a mile in length from a Phœnix dynamo at the works of the above-named firm in Wade-lane.

The New York Conduit.—The first wires to be actually placed in the New York conduit have been those of the Fire Telegraph system, for which 920ft of a six-wire cable have just been put in. The work of drawing in proved at first more difficult than had been anticipated, but became easier as experience was gained. It is anticipated that by the 1st of January ten miles of the conduit will have been constructed.

Elberfeld, Prussia.—The municipality of the large manufacturing town of Elberfeld have recently taken the vote of the inhabitants of the central district upon the question of establishing a public electric lighting installation. The replies have been almost unanimously in favour of the project, which will therefore be carried out. We presume that the Edison system will be adopted, as in so many other town installations upon the Continent.

Digitized by Google

THE SOCIETY OF ARTS.—The first meeting of the one hundred and thirty-third session of the Society of Arts will be held on Wednesday, the 17th inst., when the opening address will be delivered by Capt. Douglas Galton, C.B., D.C.L., LL.D., F.R.S., chairman of the council. As arranged at present, on December 8th, a paper will be read by Major-General C. E. Webber, R.E., C.B., on "Glow Lamps, their Use and Manufacture."

A SINGULAR PROCEEDING.—We quote the following incident verbatim from a New York journal:—" The manager of a telegraph company in New Haven, Connecticut, has gained considerable notoriety by evading the law relative to the erection of poles in public streets. On Sunday, October 17th, two enormous telegraph poles, one ninety and the other eighty-three feet in height, were erected without interference. Had this been done on any other day an injunction would have been served."

MOTIVE POWER FROM ARTESIAN WELLS.—A flour mill in New Jersey is supplied with electric light by motive power derived from a turbine which is set in motion by the water of an artesian well, sunk especially for this purpose. Artesian wells have recently been sunk in several parts of London in order to render the proprietors independent of the water companies. Wherever the rise and the quantity of flow is sufficiently great, these fortunate individuals are probably in a position to provide themselves with electric light at a very low cost.

THE UNITED STATES PATENT OFFICE.—We have received a copy of the annual report of the United States Commissioners of Patents for the year 1885. This is a very bulky volume, consisting of upwards of 700 quarto pages. The greater part of the contents consists, however, of an alphabetical list giving the name, residence, and invention of each applicant for a patent. The number of applications filed during the year was 34,697, of which only 24,104 were actually granted. Of the latter number 549 were issued to citizens of this country.

THE BRIGHTON ELECTRIC LIGHT COMPANY.—We have received the report of this company's operations for the twelve months ended 30th September, 1886, which shows a profit of £516. 16s. 5d., out of which the directors recommend a dividend of 4 per cent.—requiring £289. 12s. The amount written off for depreciation is £200, the plant being given as an asset valued at £4,627. 15s. 6d., premises at £1,793. 3s. 8d., and circuit at £757. 5s. 5d. Considering these figures the depreciation seems scarcely sufficient. The second ordinary general meeting was held at the offices of the company on Wednesday, November 10th.

ALTERNATING CURRENTS IN AMERICA.—At the present time alternating currents are so little used in the States that a paragraph with the above title might almost paraphrase the famous chapter on the snakes of Iceland, which merely stated that there are no snakes in Iceland. One of our Trans-Atlantic contemporaries is, however, of opinion that alternating currents are likely to come into use more and more. From the tenor of the article it seems that our American friends have as yet scarcely realised the full extent of the differences between continuous and alternating currents, and the extreme importance of the influence of the periodic time in the latter case.

ADDITIONAL ADVANTAGES FOR TELEPHONE SUBSCRIBERS. The Telephone Exchange at Brussels has undertaken the performance of a new and important service. Such of their subscribers as may desire it are supplied with electric bells in their bed rooms, which are rung at an appointed hour in the morning by a currect from the exchange. The subscriber is bound to turn out of bed to switch off, so that the arrangement possesses some advantage over an ordinary alarum clock, which sounds only for a limited time. It is stated that most of the leading merchants in Brussels are now taking advantage of the service, and a hitherto unheard of punctuality is said to prevail in the offices of the city.

THE GOVERNMENT AND TELEPHONES.—In answer to a deputation from the Edinburgh Chamber of Commerce, on the 4th inst., Mr. Balfour, the Secretary for Scotland, said that as to telephones, he had not a matured opinion on the subject, but he entirely agreed with the objections to any monopoly being created in them which the Government might afterwards be required to purchase; but when the Government bought up the telegraph system they secured that they should have absolute control over the sending of messages by electricity, and no one was able at the present moment to establish a telephone without a Government licence, so that there was not the slightest chance of any monopoly.

BIRMINGHAM PROVISIONAL ORDER.—At a meeting of the Birmingham Town Council on the 9th inst. a report from the Town Clerk was read advising that as the Incandescent Electric Lighting Company had taken no steps under the Provisional Order granted to them in 1883 to introduce electric lighting into the town, the Board of Trade should be asked to revoke the order. The report pointed out that the company had been unable to obtain the capital required; but meanwhile they monopolise what is probably the best area in the town for electric lighting. It was agreed that the Board of Trade be asked to revoke the Provisional Order. It will be seen that the action of the Council has not been dictated by any hostility towards the electric light.

THE LOWTHER TELEPHONE.—A telephone transmitter of a somewhat novel and curious order is now being shown in Chicago. Instead of speaking directly to a diaphragm, the operator holds a sort of button connected to a flexible wire to the side of his throat while talking. In this way perfectly articulate speech is transmitted, the tone is said to be much fuller and louder than with any instruments of the diaphragm class, and the *timbre* of the voice is better preserved. Another advantage is that whatever external noises may be going on, no sound but that of the speaker himself will be transmitted. If preferred, the button may be applied to the top of the head, or indeed to any other part of the skull, but the articulation, though still clear, is not so loud. The tip of the nose is not recommended.

LONG DYNAMO RUNS.—After quoting from our columns a note as to a continuous run of twenty-eight days which was recently performed by a Kapp dynamo on board H.M.S. "Devastation," the New York *Electrical World* proceeds to cap the story as follows:—"This recalls a phenomenally long Edison run. In February, 1884, a plant was put in the Post Office, Boston, consisting of two of the first type of 250-light machines. Without any previous testing—such was the urgency of the case—they were started, and were operated continuously for ninety-seven days and nights, when the capacity of the plant was increased without any interruption in supply of current to the circuits. The supply has not ceased, either day or night, from its going into operation in February, 1884, down to the present time."

THE TELEGRAPH IN HOLLAND.—The following statistics as to the telegraph system in Holland appear in the *Journal Télégraphique*:—The total number of stations open at the end of 1885 was 595, there were 4,700 kilometres of lines, and 16,780 kilometres of wire. About one half of the total length of

Digitized by Google

lines traverse the banks of canals and the rest is chiefly on the railways. The number of offices open is 595, of which 303, including 72 telephone stations belong to the State and the remainder to private companies. There is one telegraph office for every 9,025 inhabitants of the country. The number of instruments in use upon the State lines was 712, of which there are 530 Morse, 45 Hughes, 2 Meyer quadruplex, 2 Estienne, and 133 telephones. In the year 1885 the number of messages passing over the State lines was 3,444,698, being an increase of 123,829 over the preceding year.

ELECTRICITY IN THE CEMETERY.—We mentioned a short time since that a society had been formed at Brooklyn for the prevention of premature interment by the adoption of a system of electric alarm. It is now stated that the idea has actually been carried into practice at Sandusky, Ohio, by the following means :—Metallic rings are placed upon two adjoining fingers of the corpse in such a way that the slightest movement would bring them iuto contact, and thereby complete an electric circuit in which is placed a bell and a set of annunciators to show the number of the vault from which the signal comes. The bell is placed over the bed of the cemetery-keeper, so that he may be in instant attendance if required. This seems rather a gruesome idea (especially for the cemetery keeper), but if actually carried out on any extensive scale the experiments will be of extreme value in settling the horrible suggestions which have sometimes arisen as to the prevalence of premature burial.

ELECTRICITY AND AGRICULTURE IN RUSSIA.—The proprietor of the Russian journal, *Selsky Khosiane*, has recently made an enterprising and philanthropic attempt to bring electricity to the assistance of the struggling and distressed agriculturists of Southern Russia. It is stated that the Russian wheat growers are being absolutely ruined by American and Indian competition, and that their only chance is to thrash out their grain and place it on the market for export at the earliest possible moment. It is therefore extremely desirable that thrashing operations should be prolonged as late as possible in the evening. But to thrash by the aid of oil lamps, with loose straw all over the place, is simply to court disaster. To meet this difficulty the proprietor of the *Selsky Khosiane* has interested himself in the introduction of electric light. The Stepanoff primary battery, which is described as a modification of the Daniell, is said to have been used at Riazin with much success. Two or three lamps of 8 candle-power are found sufficient.

ELECTRIC MOTORS IN THE STATES. — A correspondent writes to an American journal as follows :—"When in New York a few days ago, I was much impressed by the large number of electric motors in use there, in connection with small manufacturing plants, elevators, and for a variety of other purposes. The enthusiasm exhibited by the users of these motors is surprising. I talked with the proprietors of a number of establishments where these clean and untroublesome little machines were doing daily work, and in every case they were not only satisfied but delighted. The dirt and bother from fuel and ashes are avoided, no expensive plant is necessary, and the work required to be done is accomplished n the most satisfactory manner possible-" We commend this paragraph to the attention of those gentlemen who have lately been interested in a scheme for the distribution of power in Birmingham, a scheme which we understand to have fallen through for the present.

LIGHTING OF A FLOUR MILL AT BOROUGHBRIDGE.—A correspondent of the *Leeds Mercury* writes :—"On Tuesday evening the flour mill of Messrs. Lofthouse and Hammond, of Boroughbridge, was thrown open to the public between the hours of six and eight o'clock, for the purpose of inspecting the working of the electric light, which has just been introduced by them into the largest of the mills, which stands on the Boroughbridge side of the River Ure. The commission has been carried out by Messrs. Christy, Son, and Norris, electrical engineers, of Chelmsford. Altogether over a mile and a half of wire has been used in the work. A Crompton dynamo of 6 horse-power is employed, and is arranged to be driven either by water or steam (both of which are in the mill). The machine runs at 800 revolutions, and supplies 50 lights of 16 candle-power, and one of 50 candle power. Messrs. Lofthouse and Hammond express the opinion that lighting by electricity is safer than gas lighting, and that the cost will only be one-third the amount per annum that gas cost them.

THE BARTHOLDI STATUE INSTALLATION.—The fifteen 6,000 candle-power arc lamps by which the statue of "Liberty Enlightening the World" is enabled to enforce the metaphor are supplied with current from an "American" dynamo, which is driven by an Armington and Sims engine, the machine being placed in a small shed at the foot of the pedestal. The dynamo runs at 870 revolutions, giving 30 amperes, at an E.M.F. of 700 volts. This is only 1,400 watts per lamp, without allowing for loss in leads, so that the arcs must have a high efficiency if they give the full nominal candle-power. The machine has an internal resistance of 3·5 ohms, and an electrical efficiency of 91·5 per cent. The total weight of the machine is 3,700lb., the armature carries 240lb. of No. 9 copper wire, and the field-magnets are wound with 640lb. of No. 5. The total electrical horse-power in circuit is 32, and 35 horse-power are required at the dynamo pulley. Duplex lamps are employed, of the "American" type. They burn Wallace copper-coated carbons, $\frac{3}{4}$in. diameter, with $\frac{1}{4}$in. arc; the E.M.F. per lamp is 38 volts, which, with 30 amperes, is equal to 0·19 watt per candle.

FLUORESCENCE FROM ELECTRIC DISCHARGE.—We recently mentioned that M. Lecoq de Boisbaudran is engaged in an investigation upon the fluorescence of different substances under the electric discharges in a vacuum. The following are some of the results which have been obtained :—Sulphate of lime, after being heated to a dull red, gives a feeble fluorescence with a continuous spectrum; but when MnO, SO_3 is added it furnishes a beautiful green tint. With $\frac{1}{100}$ part of this salt the effect is very fine and with $\frac{1}{20}$ it is superb. The spectrum is continuous, but contains little red or violet. Carbonate of lime gives fluorescence *in vacuo* after strong calcination and a violet tinge at the electrodes. With carbonate of lime, rendered manganiferous, there is an orange fluorescence after calcination; sulphate of magnesia, after being heated red a little, gives a feeble fluorescence of a greenish white, with continuous spectrum. Pure carbonate of magnesia gives no notable fluorescence after strong calcination. Similarly, carbonate of magnesia containing a little carbonate of manganese, furnishes fluorescence. Sulphate of zinc, after heating to dull red, gives a feeble fluorescence of a pale rose colour. Sulphate of cadmium, oxalate of strontium, and some other salts, also yield a fluorescence in vacuum.

TELEPHONING WITHOUT WIRES.—The problem of effecting electrical communication without the use of metallic connections has long been known to be within the limits of theoretic possibility, and indeed, it has more than once been actually accomplished. While, however, it is proverbially rash to prophecy, and more especially to attempt to assign a limit to the achievements of the future, we shall venture to assert that

Digitized by Google

the day is far distant when electric communication without wires will become general, if only because it is obvious that the problem involves all the difficulties of multiplex telegraphy on the most gigantic scale. Prof. Dolbear has, however, designed an arrangement for telephoning between two given points without wire, and states that it can be successfully employed over distances exceeding half a mile. His plan amounts to this: A condenser at one station is charged from a battery in the circuit of which a telephone transmitter is included; one pole of battery is connected to earth, and one pole of the condenser remains free and disconnected, so that the battery, which should contain at least 100 cells, is really on open circuit. A similar arrangement exists at the other end of the line, only that in the circuit in which the receiver is placed the opposite pole of the battery is connected to earth. When the transmitter is spoken to, the disturbance of the potential of the earthplate is sufficiently marked to affect the receiver at the distant end. From a practical point of view, a serious difficulty would arise from the inability to transmit a call signal on this system.

Evening Lectures at the Finsbury Technical College. We have pleasure in calling attention to the following circular: The following course of instruction has been arranged to meet the wants of machinists, ironmongers, bicycle makers, lamp makers, electroplaters, and others who desire to obtain theoretical and practical knowledge of the processes of electro-deposition of metals. The six lectures of this course will be delivered by Prof. Silvanus P. Thompson, on Thursdays, at 8 p.m., at the Finsbury Technical College, commencing Thursday, 8th of November, 1886. This course of lectures is devoted to the modern practical processes of nickel-plating, steel-plating, coppering, electrobrassing, electroplating with silver, electro-gilding, &c. Special attention is paid to the use, in plating, of the dynamo-electric machine. A course of practical laboratory instruction is provided as supplementary to the lectures, under the superintendence of Mr. E. Rousseau, and the demonstrators of the electrical department. Students entering for this course will be divided into groups, each group receiving independent instruction:—I. November 18th, "General Principles of Electro-chemical Deposition; Fundamental Experiments on Electrotyping and Electroplating." II. November 25th, "General Principles of Electric Currents; use of Galvanometers." III. December 2nd, "Electro-deposition of Copper; Electrotyping; Silver-plating; Electrobrassing; Electro-gilding." IV. December 9th, "Nickel-plating; Steel-plating; Deposition of Cobalt and of Aluminium." V. December 16th, "Preparation and Testing of Plating Solutions." VI. December 23rd, "Dynamo-machines for Electro-deposition." We may add that the fee for this course, including laboratory instruction, is only 6s., while apprentices are admitted at half fees.

A Magnificent Idea.—The paragraph which we reproduce below appears in a north country paper. As the gentleman referred to may be assumed to take an intelligent interest in electrical matters, it follows with a high degree of probability that he will be a reader of *The Electrician.* We therefore take the earliest opportunity of doing Mr. Quarrie the greatest service in our power, and beg to assure him that in our own opinion—which he may take for what it may be worth—some of his ideas are scarcely in accordance with the generally received views as to sound and practical electrical engineering. "Mr. George Quarrie has invented certain improved apparatus designed for the production of electricity. His plan is to utilise rotating shafts in mills and steamboats, railways and tramcars, upon which to affix generators which will throughout the day be ceaselessly collecting and storing electricity for use when darkness comes on. He further proposes to utilise the two natural forces of wind and moving waters to produce a continuous flow of the electric current, on the principle of Faraday's discovery that if a magnet is dipped just inside a coil of copper wire, and suddenly withdrawn, a current of electricity is generated. For the supply of a city or town the streets will be crossed by minute rails, whose vibration by the crossing traffic would be a large source of the current in the same way; (!!) and the inventor considers it possible to supply every house and street of town and country with all the light they want at a cost of a very small fraction of that paid for anything now in the market for that purpose. It is stated that one large factory and a steamship company have arranged with Mr. Quarrie to have the system immediately adopted in the works and in one steamship as practical trials."

The Electric Light at Tavistock.—The *Western Morning News* of Nov. 6th contains the following paragraph with reference to the Thomson-Houston installation, which Messrs. Laing, Wharton, and Down have recently established at Tavistock:—"The electric light as exhibited at Tavistock during the past week has proved a signal success, and has been nightly watched by large and interested crowds. Yesterday being market day, large numbers of persons from the country places remained in town for the purpose of seeing what the illuminations were like, and were well satisfied with the results shown by the proprietors, who went through a series of experiments in lighting and turning off the light and then relighting. There are now eleven arc lamps in various parts of the town, and they are all giving a splendid illumination. Arrangements were being made yesterday (Nov. 5) for lighting the parish church on Sunday evening next, the wires having been already carried into the edifice for that purpose. The shop of Messrs. Cundell and Camozzi, of Duke-street, was also illuminated last evening with marked success, and large numbers of persons witnessed the experiments of Mr. Cundell in turning out and again producing the light. On Sunday, the 14th, the Congregational Church is to be illuminated, and various shops will also be lighted during the coming week. Mr. Wharton will shortly lecture in the Town Hall on the advantages of the electric light, and will then explain and show how easily it may be used. The hall will be lighted by electricity on the occasion." We trust that the good people of Tavistock will have the enterprise to seize the opportunity of distinction which is now offered them, and will arrange with Messrs. Laing, Wharton, and Down for a continuance of the "experiments of turning in and out the light" every night in perpetuity.

The Distribution of Power.—The following are the views of a Boston (U.S.) manufacturer on this subject. To a certain extent the statements must no doubt be taken *cum grano salis*, but they are probably not very far wrong:—"The transmission of power from small central stations for small distances by means of wire ropes, shafting, &c., has been done for years, and so profitable has it been found to be that many of the wealthiest and shrewdest business men in Boston have been engaged in it. Steam plants of 50 or 75 horse-power have been placed in many blocks to furnish power for elevators, pumps, fans, and machinery, and the power is sold at the rate of $150 per horse-power per year; in many cases a higher rate is obtained. I have investigated the subject, and find that electric current, as sold for lighting purposes, is charged at the rate of $300 per horse-power per year; while from the same stations the rate for electric-motors is $125 per year per horse-power. As the use of the motor is by no means constant, double the amount of power can be sold; that is, the capacity of the station. Here is the estimated cost and profit of a power

Digitized by Google

station :—160 horse-power boilers, 140 horse-power in engines, 2 dynamos capable of generating current equivalent to 100,000 watts, wires, &c., $17,000. Two hundred and eighty horse-power may be sold, as is shown by experience of those renting steam-power. There is no expense for motors, as each user owns his own. Income from rental of power, $125 × 280 = $35,000, running expenses, say, $8,000, leaving a profit of $27,000, which is more than 150 per cent. on cost of plant If the station furnished current for lighting purposes during the evening, the percentage of profit could be largely increased. Burning cheap fuel under the best conditions, $15 can be made to buy enough coal for one horse-power per year. An electric method of transmitting power has the great advantage that points twenty times as distant from the source of power can be reached as when belts, ropes, shafting, are used. Four hundred times the area can be profitably covered by an electric system as by a steam plant. Wire ropes, belts, &c., are expensive, and wear rapidly. The copper conductor suffers no depreciation whatever."

A STEP IN THE RIGHT DIRECTION.—The United Telephone Company have at last determined upon a step which will go far to remove from their shoulders the reproach of lack of enterprise which has long rested upon them. They are now actively engaged in canvassing the district of Kensington, with a view to the establishment of a local exchange upon the American plan of a telephonic syndicate. The idea will be understood from a perusal of the following circulars, which we quote *verbatim*. The first is issued to the tradesmen of the district, as follows:—"Sir: The immense success which has attended the system of local telephonic exchanges in America has led the directors of the United Telephone Company to sanction an experiment in this direction at Kensington. It is proposed to connect a number of the principal residences—say one hundred—with a local exchange, and to allow the tradesmen in the district to use the system for a payment of £1 per annum for each house, and £1 extra should the amount of orders by telephone from any one house exceed £100 in the year. The saving in the annual working expenses of your business will be great, irrespective of the large accessions of business which you will receive for a merely nominal payment *(less than three farthings a day)*. Should you be disposed to join the *first* syndicate now in course of formation, I shall be glad if you will fill in the enclosed form with the addresses of any private residences with which you would like to have telephonic communication." The second is issued to private residences, and reads as follows:—"Sir: The directors of the United Telephone Company having sanctioned the establishment of a local exchange in Kensington for the purpose of connecting first-class residences with the local tradesmen, I shall be happy to receive from you, should you desire to have such telephonic communication, the annexed form filled up with the names of those tradesmen with whom you would wish to be in communication. It is not intended that you should be put to any expense, as the company will place the instruments in private residences free of all charge to the occupiers. The residents will thus be placed in instant communication with any tradesman on the list, as well as with their medical man, chemist, &c., so that assistance in case of illness or accident can be summoned without delay. The inmates of any of the private residences connected with the exchange will also be able to converse with any of their friends whose houses are similarly connected, and will also be able to call a cab from the nearest cab stand, or give an alarm to the fire and police office of their district." Here follows a list of trades—the butcher, the baker, the candlestick maker, and so forth, against which the names of the firms with whom connection is desired are to be filled in. We congratulate the residents of the Kensington district upon their good fortune. We only hope that the result may prove so satisfactory to the company as to induce them to extend the system all over the suburban districts. We do not, however, quite understand the financial side of the question. If each of the tradesmen is to pay £1 upon every connection made, the company will realise a very substantial revenue.

TELEPHONIC SYNDICATES.—The following appeared in the *Western Morning News* last week:—"'I have been asked to join a telephonic syndicate, and I want to know what it is?' Thus inquired a friend of mine the other day. Now, I do not know much about syndicates generally, except that some men who suddenly rise from mediocrity to opulence tell me they have joined a syndicate and made a nice pile out of it. But a 'telephonic syndicate' I do know a little about, and as my friend is very likely to be only one of many who thirst for knowledge, I will try to explain the sort of thing he has been asked to join. 'Shopping' is one of the wearisome institutions of civilisation. I often want some article or another, and yet for weeks leave the shop unvisited simply because to a busy man like myself time is so valuable. So much for me. But my wife? Butcher, baker, poulterer, greengrocer, fishmonger, dairyman, and I know not how many more, call for orders every day, and all the morning is spent in answering the maid, who comes to say, 'Please, 'm, the butcher,' or 'Please, 'm, the greengrocer.' If my wife can order by telephone, the tradesman is relieved of the expense of sending for orders, and hers and the maid's time is saved. What a blessing it would be! Good. But a telephone costs £20 a year. Here comes the agent of 'a syndicate,' or association of the sharp tradesmen in my neighbourhood, and says that a telephone will be fitted up if I will give—what? My permission! These traders find it so much to their advantage to have orders by telephone and save time, that they have united to furnish a hundred houses in the district with the time-saving instrument gratis. On the telephone hangs a card, and on the card are printed about twenty tradesmen's names, who form the syndicate. Finn the fishmonger, Jones the baker, and all the other leading men, the sharp, shrewd fellows who know the innate laziness of the Briton's constitution, and by saving me trouble, gain trade for themselves, here they are, set down in order, and without stirring from the house, we can command an army of ready caterers. In cases of interesting domestic emergency, or of accident, there are the doctor and the chemist on the list. Nor is this all. I have a cold, perhaps, and cannot go to town. Here is the rub. This telephone is on a small 'primary exchange,' and how can I call to 7,654, for instance, on another exchange? The local syndicate give me their instrument, but it is obvious that for me to call someone not connected with the syndicate entails expense. Very well. All that is arranged, I call my local exchange, they switch me on to the trunk line, and so to 7,654, my town office, and debit me with threepence for the message—not of twenty words, but of whatever length may suffice for the business in hand. The syndicate pays well. What the traders pay is not, be it well observed, an actual outlay, but really only a commission on orders received by telephone. In my friend's neighbourhood several firms have expressed their willingness to pay 5 per cent. on such orders. Telephone enterprise is old enough to be secure from idle opposition and the effects of panic, and yet quite young enough to show fine promise of a grand future. So, my advice to my friend, was 'join the syndicate.' It is beyond all question a capital idea, and its successful adoption in many parts is encouragement to the sharp tradesmen in all localities to follow the lead, to oblige their customers and to fill their own pockets."

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

MAGNETISM AND ELECTRO-MAGNETISM.—I.

The property possessed by the natural magnet or lodestone of setting itself in a definite direction when freely suspended appears to have been known in very early times by the Chinese and Egyptians. The word magnet was applied to the lodestone on account of its being found in Magnesia. There are two districts known as Magnesia, one in Lydia and the other in Thessaly. It is from the former that the magnet appears to have derived its name.

The power of the lodestone of attracting pieces of iron was known in Europe in early historic times, and Lucretius found that the attraction was exerted through brass as readily as through air. The tendency of the lodestone to set in a definite direction was not known in Europe till a much later date.

If a piece of lodestone be dipped into iron filings, it will be found that the filings will cling in tufts to the lodestone, and that these tufts will be largest around two regions of the surface. If the lodestone be suspended so that it can turn freely in a horizontal plane, it will place itself so that one of these regions is directed nearly to the north and the other to the south. These regions were called by Gilbert the poles of the magnet, and a line joining the poles he called the magnetic axis. That pole which points towards the north we shall call the north pole, and that which points towards the south the south pole. According to this nomenclature the magnetic pole of the earth in the neighbourhood of the geographical south pole is a magnetic north pole, and those in the neighbourhood of the geographical north pole are magnetic south poles. To avoid this apparent anachronism some persons speak of the north-seeking pole and the south-seeking pole. Others call the north-seeking pole the magnetic south pole, while others again employ terms of a purely arbitrary character to distinguish the poles, as, for instance, the red and blue, calling the north-seeking pole the red pole and the south-seeking pole the blue pole. Sometimes the magnetic pole, which is of the same kind as the south pole of the earth, is called the Austral pole, while that which resembles the earth's north pole is called the Boreal pole.

If a steel bar be rubbed with a lodestone, it will generally be found that the bar has acquired magnetic properties, and if freely suspended will set with one end pointing towards the north, and the other towards the south. If the bar were drawn across the north pole of the lodestone, that end of the bar which was last in contact with the lodestone would be a south pole. The steel bar so magnetised will be found capable of imparting magnetism to another bar, if the other bar be drawn across one of its poles several times, but always in the same direction. In this way magnets may be multiplied indefinitely.

Suppose a bar of soft iron to be placed with one end near to the north pole of a steel magnet or a lodestone. The iron bar will be found capable of attracting small pieces of iron at each end. In fact, the bar is converted into a temporary magnet, by influence, or induction. If the soft iron bar be removed from the presence of the magnet, it will be found to have lost nearly all the magnetism which was imparted to it.

If a bar of hard iron or of steel be employed, instead of the soft iron bar, the magnetism induced is much less, but if the bar be hammered, or in any other way violently shaken, while under the induction of the magnet, the bar will become permanently magnetised. The property in virtue of which hard iron or steel resists the magnetising influence of a neighbouring magnet is sometimes called coercive or coercitive force, and this same property enables the steel to retain its state of magnetism after the magnetising force has been removed.

The magnetisation of a steel bar by drawing it across a pole of a magnet is a phenomenon of magnetic induction in which the induced magnetism is rendered permanent by "coercive force."

It has been found possible to retain a very high degree of magnetisation in soft iron by treating it with sufficient care. A very slight amount of mechanical violence after the magnetising force has been removed causes the iron to lose nearly all its magnetisation. Assuming that magnetisation means a displacement of the molecules of the substance, it would seem that this elasticity of the material tended to bring them back to their original positions, and the act of magnetisation consisted in the production of an elastic strain. In very soft iron the displacement of the particles is resisted almost solely by the elasticity of the material, but in harder metal and in steel there is a very great resistance to the relative motion of the molecules, of the nature of friction, and this frictional resistance is greater the harder the metal. As is always the case with friction, the tendency of this "coercive force" is to resist change of state of any kind, and therefore to make it more difficult, on the one hand, for the magnetising force to induce magnetisation in the metal, and, on the other hand, for the elastic forces to destroy that condition when the magnetising force has been removed. If the magnetising force is very great the state of strain induced may also be very great, and when the external force is removed the elastic stress will be far more than sufficient to overcome the frictional resistance, and the material will return partly towards its original state, so that for a given material there will be a certain degree of magnetisation which it will be able to retain, and, however strong the induced magnetisation, that permanently retained will not exceed this limit. But if the material is subject to mechanical violence a new action comes into play. Place a small body upon a board and slightly slope the board, so that the body is retained on the inclined plane by friction. If not subject to vibration the body will remain at rest indefinitely; but if the board be struck lightly with a hammer the body will gradually creep down the plane. In all experimental illustrations of the elementary principles of statics friction interferes very much with the accuracy of the results unless proper precautions are taken; but by subjecting the system to vibrations gradually diminishing in intensity it will at length assume the same condition as if no friction acted upon it, and the relations between "the power and the weight" may thus, in many cases, be accurately obtained. Vibrations if sufficiently intense to relieve for an instant the normal pressure between surfaces in contact will, when constantly repeated, produce the same effect as the complete removal of the friction. It is for this reason that lock nuts are required in machinery, though the necessity for their use may be obviated when the pressure of the nut on the screw can be made so great that no vibration to which the part is exposed can release it. The same principles apply to magnetisation. If, while under the action of the magnetising force, the metal is lightly tapped, the effect is to diminish the influence of the coercive force and to enable magnetisation to be induced. On the removal of the magnetising force similar vibrations give full play to the elastic forces, and cause the metal to resume its normal state, so that steel magnets should be protected as far as possible from mechanical violence. The vibrations to which iron ships are subjected while on the stocks cause them to assume a permanent state of magnetisation through the influence of the earth, and to this permanent magnetisation is added any temporary magnetisation which may subsequently be induced in the structure.

The nature of coercive force explains the necessity of causing the steel bar which is to be magnetised to move over the pole of the inducing magnet, or to cause the pole of the magnet to move over the bar. By this means each portion of the bar in succession is brought into close contiguity with the pole, and therefore into a very intense field of force. The coercive force is thus overcome, and the molecules made to obey the magnetising force, and this action takes place in each section of the bar in succession. That the act of magnetisation consists in the displacement of the molecules is rendered probable by the observed fact that an iron bar when magnetised expands in the direction of its magnetisation and contracts laterally, provided it is not exposed to severe tension. By simultaneously magnetising a tube longitudinally and circumferentially a torsional strain can be induced in the tube. If an electro-magnet be introduced into the circuit of an alternating current dynamo, the alternate magnetisation and demagnetisation of the iron cores cause them to emit a loud musical note, due to their

Digitized by Google

expansion and contraction. With a dynamo whose currents alternate two or three hundred times in a second, it is perfectly safe to introduce a large electro-magnet of very small resistance into the circuit, without any other resistance, for the "self-induction" of the magnet, a property to be explained later on, will effectually prevent the currents from rising above a very small limit.

If a steel bar, magnetised in the direction of its length, be plunged in iron filings, the filings will cling to the bar, mainly around its ends. At the middle of the bar there will be no attraction exerted upon the filings. If two bar magnets be brought near to one another, they will act as though the whole of their magnetism were concentrated at points very near the ends of the bars. Thus, the action of a magnet upon another magnet at a distance is very nearly the same as if its magnetism were concentrated at two points near its ends. These two points are the magnetic poles.

The accompanying cut shows the arrangement of the filings around a bar magnet (Fig. 1).

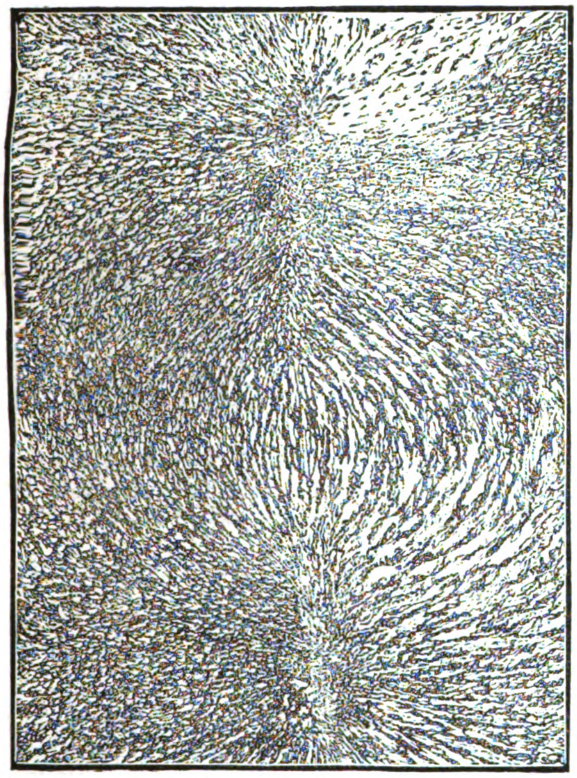

Fig. 1.

Fig. 2 shows the lines of filings near two attracting poles, Fig. 3 the lines near two poles which are repelling one another. If we suppose a tension to be exerted along the lines of filings, and a pressure at right angles to these lines, the diagrams at once indicate the nature of the stresses.

If it were possible to magnetise a bar uniformly throughout its whole length the poles would be found situated on the end faces of the bar, and no lines of filings would adhere to the bar except at its ends. It is not possible, however, to produce such uniform magnetisation, and we consequently find north polarity extending over one half of a bar magnet, and south polarity over the other half, the centre of the bar being the only neutral position; but the polarity diminishes rapidly as the centre is approached, and is generally very feeble at points more than one-third of the length of the bar from each end. This is well shown in Fig. 1, for polarity exists wherever lines of force enter or leave the bar.

If an elongated conductor be exposed to the inductive action of an electrified body placed near one end, the conductor will be charged at the one end with negative and at the other end with positive electricity, and there will be a neutral line, or line of no electrification, near the middle of the conductor. If the conductor be divided along this neutral line and the parts separated, one end will be found negatively charged and the other positively charged. But if a bar magnet be divided across its neutral line, the two parts will not be found to be oppositely magnetised, the one consisting of a north pole only, and the other of a south pole, but each portion will be found to be a perfect magnet, having its poles in the directions

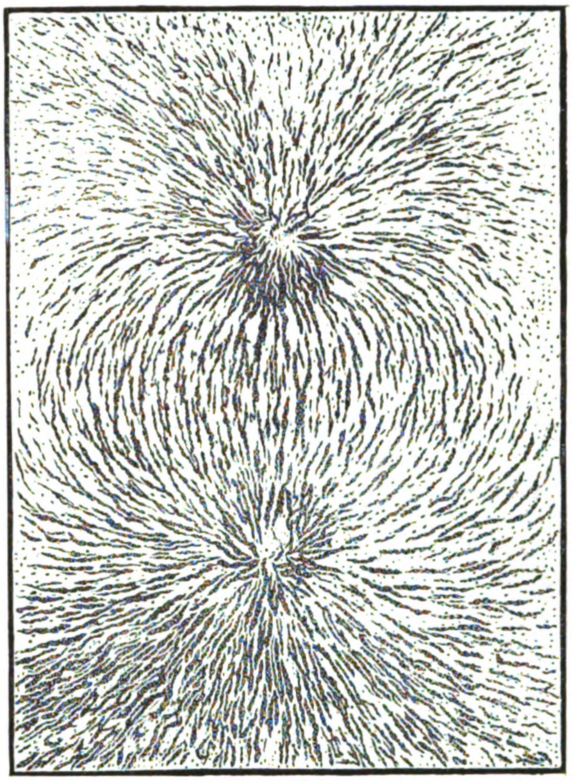

Fig. 2.

of the poles of the original magnet, and nearly equal to them in strength.

Similarly, if a bar of soft iron be placed with one end near a pole of a magnet it will become magnetised by induction, its

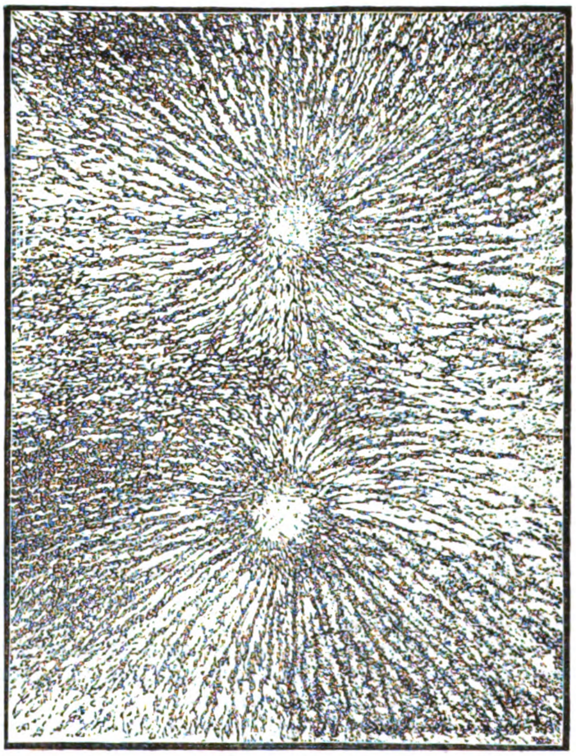

Fig. 3.

two ends being opposite poles, but if the bar, while still under the action of the magnet, be divided across the middle and the parts separated by a small distance, each part will be found to be a complete magnet with opposite poles, and will remain such

Digitized by Google

as long as it is under the inducing action of the permanent magnet. It will be noticed that the pole in the iron bar which is nearest to the inducing pole will be less spread over the surface of the bar than the other poles, or the magnetism will appear to be more concentrated at that pole.

Fig. 4 represents the arrangement of filings around a bar of soft iron when acted on by the pole of a magnet. It should be noticed how the piece of iron appears to draw the lines of force of the magnet towards itself, and how these lines after entering the iron at the end near the magnet leave it again at the sides and at the other end. The poles of the piece of iron correspond to the portions of the surface where the lines of force enter or leave it.

To account for the invariable occurrence of opposite poles, it has been supposed that every particle of a piece of iron or steel is itself a magnet, having north and south poles, but that when the metal is in the ordinary, unmagnetised condition the magnetic axes of the particles point in all directions. The operation of magnetisation consists in imparting to the magnetic axes a general inclination towards one direction,

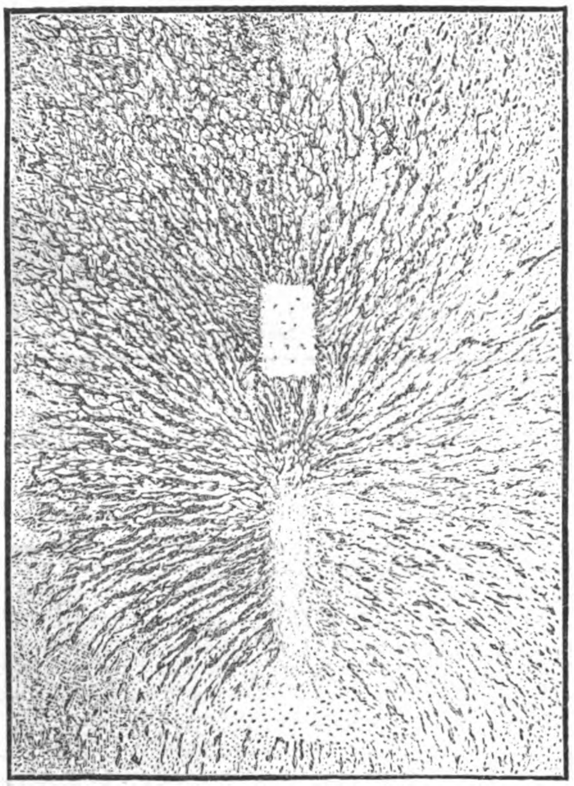

Fig. 4.

which is that of the magnetic axis of the whole magnet. If the particles are turned so that they all have their axes parallel, the metal is magnetised to the fullest extent to which it can attain. In general the magnetic axes are not all parallel, but simply have a tendency towards one direction. This theory is illustrated by taking a tube of glass, or some other non-magnetic substance, and filling it with iron filings. If the tube be now drawn across a pole of a magnet it will be found to be magnetised, just as if it were a solid bar (though less strongly). If the filings now be turned out and then replaced, the tube will show no trace of magnetisation, for the magnetised particles will have their axes turned at random in all directions.

Two magnets behave towards one another as though their poles were centres of force. The law of magnetic action is similar to that of electrical action, viz.:—

Like poles repel, and unlike poles attract one another with forces which are directly proportional to the product of the strengths of the poles, and inversely proportional to the square of the distance between them.

From this law the action of one magnet upon another can be determined by calculation.

(To be continued.)

TESTING DYNAMO MACHINES.

BY JAS. SWINBURNE.

Introductory.

In the discussion upon the paper by Mr. Kapp at the Institution of Civil Engineers last November, Dr. Hopkinson proposed a method of testing dynamo machines that reduced the error due to the inaccuracy of mechanical dynamometers. Dr. Hopkinson has since worked the system out very thoroughly, and has thus put electrical engineers in possession of a most valuable means of measuring the efficiency of dynamos. Dr. Hopkinson's method has been very fully described in the various technical journals, so it is enough to say that it consists in coupling a dynamo and a motor together rigidly, and connecting them together electrically also, so that the mechanical power given to the dynamo by the motor is partly returned as electrical power to the motor. The loss of power in both machines is made up by supplying mechanical power by a belt from a small subsidiary motor. This power is measured by a dynamometer, and as it is only a small fraction of the whole power a slight error in this determination becomes very small in comparison with the whole power transmitted by the large motor. The publication of the tests of the machines at Messrs. Mather and Platt's works brought out the fact that Captain Cardew had already been in the habit of testing dynamos and motors by a method similar in principle to Dr. Hopkinson's, with the advantage of dispensing with all mechanical dynamometric readings. Captain Cardew coupled a dynamo and motor together by a belt, and fed the motor entirely from an outside source, and ran the dynamo into resistance. This method is capable of great accuracy in measurements, but it has the drawback of needing three large dynamos to make a test, and this is not always easy to arrange. Captain Cardew does not seem to have realised that his system was capable of such great perfection, and appears to have merely measured the loss of power electrically, and to have split it between the two machines. Captain Cardew's method will be more fully described in connection with some tests recently carried out at Enfield Ordnance Factory.

About the time of the Manchester tests the writer discussed with Mr. Crompton various ways of modifying Dr. Hopkinson's method, so as to get accurate tests without the use of a mechanical dynamometer and without waste of power, by coupling the motor and dynamo together both electrically and mechanically, and supplying the loss of power electrically, so that all the measurements should be electrical. This method was brought before the Dynamicables or mentioned there very soon after, by Mr. Crompton. Lord Rayleigh immediately afterwards suggested that this might be done, and Captain Cardew drew attention to his method at the same time. Messrs. Menges, Trotter, Haynes, and others have since proposed various arrangements, and as the subject is very important it may be as well to discuss several ways of taking tests with different means at command. The writer has not any large array of experiments to produce, but his object is to explain various methods of taking efficiency tests, so that many engineers who have not two or three large dynamos at hand, and possess no transmission dynamometers or accurate measuring instruments, may be enabled to find out the value of their machines.

Before going into the details of actual testing a few words must be said on the reversibility of dynamo machines. Last winter Mr. Mordey pointed out in the *Philosophical Magazine* that the common idea that a good dynamo is a bad motor, and a good motor a bad dynamo, is wrong, and that the principle of design is exactly the same in each case. That it is so, and must be so, is obvious immediately one has his attention drawn to the point, for it is clear that if it takes a certain force to move a conductor through a given field, there is the same force available to move the conductor in an opposite direction. Mr. Mordey's theory is, like many similar things, so clear when one understands it that one thinks he has known it all the time. No doubt every electrician who read that article felt as if there was nothing new in it, though it is

Digitized by Google

really one of the most important papers that has recently appeared. But, on the other hand, there are a great many people who still think a motor ought to have much more wire on the armature, and a comparatively weak field. This, perhaps, arises from some confusion as to dynamos and motors designed to have a high efficiency, or a very light weight. A dynamo, or motor, designed to have a high efficiency is made with a strong field, and comparatively little wire on the armature. Such a machine is heavy, and consists chiefly of iron. If a dynamo or motor is wanted particularly light, it is made with a small field, and more copper is wound, both on the field-magnets and on the armature. The result is that a machine is obtained which gives a large output for its weight, but has not such a high efficiency, and needs more copper. Moreover, it is liable to spark, and its brushes need to be carefully attended to if the load is varied. But in each case the design for the motor and for the machine is precisely the same. It has been said that a motor differs from a dynamo with regard to the action of its armature on the field-magnets. An analogy has been said to exist between the revolving armature and the keeper of a permanent magnet. If the keeper of a permanent magnet be quickly removed, a current is induced round the magnet, tending to strengthen it, and if quickly brought back the reverse takes place. A motor has therefore been compared to a magnet with its keeper always approaching, and a dynamo to a magnet with its keeper always being torn away. The analogy, however, breaks down completely, for though the iron of the armature moves round in the case of a machine, the field in it is stationary. There is, therefore, no such action on the field-magnets. In 1883 the writer, after seeing some articles in the French journals which assumed a back electromotive force in the field-magnets, tried the following experiment :—A small Siemens direct current machine was run, with only one magnet excited, and its full armature current. A galvanometer was put in circuit with the other two coils. There was no deflection. So close is the correspondence between a dynamo and motor that even the lead of the brushes to avoid sparking, due to self-induction, corresponds. A dynamo demands an extra forward lead, and a motor an exactly equal extra lead in the other direction.

It is very important that these points should be clearly understood, for the common misapprehension has been the cause of the manufacture and sale of a large number of very bad motors in this country, and more especially in America. When anybody wants a good dynamo he goes to some maker who has studied the subject, and who, from his experience and standing, can be relied upon to make a good machine ; but when a motor is wanted it seems to be assumed that a dynamo maker cannot make it, and someone who is supposed to have made a speciality of motors is got to fabricate a machine. Any manufacturer who makes a good efficient dynamo can make an equally good efficient motor, and those makers who have worked out good types of light-weight ship machines can without further experiments make good light-weight motors. The practice of making very bad machines of extraordinary and outrageous design, on the supposition that they are therefore good motors, prevails chiefly in America, but it is not unknown in this country, and is much to be discouraged. The apparent efficiency of a motor is higher than that of a dynamo. This results merely from the way of taking efficiencies, just as 10 per cent. discount is a larger share than 10 per cent. interest. Take, for example, a series wound machine which as a dynamo gives 100 volts at the terminals, and say 746 amperes at a certain speed. Suppose there is a loss of 15 volts in the armature and field-magnets, and that the other small losses are neglected, the machine then gives out 100 electrical horse-power, and absorbs 115 horse-power at the belt. The electromotive force of the armature is 115 volts, of which 15 are lost in the machine itself and 100 given out. The efficiency of the machine is 87 per cent. as a dynamo at that speed and with that current. Suppose the machine is run as a motor at the same speed with the same current. The back electromotive force of the armature is then 115 volts, and 15 more volts are needed to overcome the resistance of the wire. The machine therefore needs 130 volts on the terminals, and it will give at the pulley, with a current of 746 amperes, 115 horse-power, which is just what it absorbed as a dynamo. Its efficiency as a motor will be 88·5 per cent. With a less efficient machine the difference would be greater.

To test a dynamo thoroughly we want to know not only the output and the efficiency, but also the exact loss of power in each part of the machine.

The whole loss is made up of the losses due to the following :—

1. Mechanical friction of the bearings, &c.
2. Foucault currents in the armature core.
3. Persistent magnetism in the armature.
4. Foucault currents in the armature conductor.
5. Resistance of the armature conductor.
6. Resistance of the field conductors.
7. Foucault currents in the field-magnets.

Most of these losses can be separately estimated. The loss in overcoming the resistance of the armature and field-magnets, for instance. can be calculated at once, but the losses by Foucault currents in the armature, core and spindle, &c., by persistent magnetism in the armature core, and by Foucault currents in the armature conductor, are more difficult to get by themselves. The effect of persistent magnetism, or, as it is sometimes called, residual magnetism or hysteresis, in the armature core, does not appear to have been much studied ; but persistent magnetism plays a far more important part in dynamos than is commonly supposed. As Lord Rayleigh remarks, it is generally confused with Foucault currents, but its existence in the armature, apart from Foucault currents, may easily be shown. If the armature of a dynamo which runs very freely be rotated by hand without the field-magnets being excited, it runs round very easily. If, while it is running round, the field is suddenly separately excited the armature is pulled up sharp. It is now found to take some force to move it round in either direction. If it is given a shove round it will quickly stop and give a kick back in the opposite direction. This effect can be due to persistent magnetism alone, for Foucault currents would not be perceptible at such a slow speed, and nothing but persistent magnetism would give the kick in the opposite direction. The Foucault currents in the armature wire cannot be separately measured. A Foucault current is a current induced where it is not wanted. In large machines these currents constitute a very important loss of power. Though they cannot be measured directly, a minimum value for a given machine may be roughly calculated, and by exploring the field by means of a pilot brush enough data may be obtained to calculate the loss very approximately. Loss of power through Foucault currents in the field-magnets is a common fault in arc light machines. There are two ways of losing power by Foucault currents in the field-magnets. One is by using an armature with teeth, such as the various modifications of the Pacinotti ring; and the larger the teeth the more serious is the waste. In such a machine, for instance, as the Brush, the pole pieces become so hot that the paint gets burnt off. As Dr. Hopkinson points out, the heating would be even more serious if the pole pieces were made of soft iron, which would offer less electrical resistance. The other source of loss of power in the fields by Foucault currents is due to unsteady currents. This, again, is generally confined to arc machines. Such armatures as the Brush or Thomson-Houston tend to give a varying current. The variation is partly corrected by the self-induction of the field-magnets and of the lamps or other appliances in the outer circuit. The self-induction of the field is lessened by persistent magnetism. Prof. E. Thomson describes the use of a layer of copper strip or wire wound on the magnets under the existing coils so as to form a closed circuit. This lessens the waste of heat, for any change in the main current produces a current in this wire which tends to keep the induction in the magnets uniform. In the case of a series dynamo the loss of heat, including that due to the current round this closed copper circuit, is less than the loss in the iron alone without it. The loss in the field-magnets with an unsteady current cannot

Digitized by Google
REESE LIBRARY OF THE UNIVERSITY

of course be found by taking the current with an ordinary ammeter and multiplying its square by the resistance of the field-magnets. It can be integrated, however, by a high resistance Weber dynamometer, without self-induction, used as a watt-meter. Foucault currents in the field-magnets are chiefly to be met with in arc machines, especially in those from the other side of the water. They may arise, however, from the arc lamps themselves, in which case they must be considered a fault in the system, not in the machine.

(To be continued.)

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XXXIII.

BY OLIVER HEAVISIDE.

(Continued from page 317, Vol. XVII.*)*

The Equations of Propagation.—Introduction of Self-Induction.

The next step to a correct formulation of the laws of propagation along wires is obviously to take account of the electric force of inertia in the expression of Ohm's law. This appears to have been first attempted by Kirchhoff in 1857. According to J. J. Thomson ("Electrical Theories," *The Electrician*, June 25, 1886, p. 138) this was his system. Let

$$e = \mathrm{X} \sin ns,$$

where e is the charge per unit length, and s is length measured along the wire. The equation of X is

$$\frac{c^2}{2}\frac{d^2\mathrm{X}}{ds^2} = \frac{rc^2}{16l\gamma}\frac{d\mathrm{X}}{dt} + \frac{d^2\mathrm{X}}{dt^2},$$

where r is the resistance of the wire in electrostatic units, l its length, $\gamma = \log(l/a)$, where a is its radius, and c is a quantity occurring in Weber's hypothesis, the velocity with which two particles of electricity must move in order that the electrostatic repulsion and the electromagnetic attraction may balance.

As it stands, I can make neither head nor tail of it. But, by extensive alterations, it may be converted to something intelligible. Turn X into e, in the second equation; or, what will come to the same thing, take V as the variable, since e and V are proportional. Then ignore the first equation altogether. Turn s into our variable x. Then

$$\frac{d^2\mathrm{V}}{dx^2} = \frac{r}{8l\gamma}\frac{d\mathrm{V}}{dt} + \frac{2}{c^2}\frac{d^2\mathrm{V}}{dt^2}.$$

Clearly this should reduce to (71*b*) by ignoring the last term. Therefore

$$r/8l\gamma = \mathrm{RS}.$$

Here r/l is the resistance per unit length. Therefore $(8\gamma)^{-1}$ should be the capacity per unit length, or $\{8 \log (l/a)\}^{-1}$. This is clearly wrong. The l should be a_2, the distance of the return, a far smaller quantity than l; and the 8 should be 2, if the dielectric is air. This last correction may, however, be merely required by a change of units. Making it, we get this result

$$\frac{d^2\mathrm{V}}{dx^2} = \mathrm{RS}\frac{d\mathrm{V}}{dt} + \mathrm{L_0S}\frac{d^2\mathrm{V}}{dt^2},$$

in our previous notation, with the addition that $\mathrm{L_0}$ is the inductance per unit length of the dielectric only. That is,

$$\mathrm{L_0} = 2\mu \log (a_2/a_1),$$

with unit inductivity; a_2 distance of return, a_1 radius of wire. This estimate of the inductance is, of course, too low. The change of units makes it doubtful whether $\mathrm{L_0}$ or some multiple of it was meant, but it is clearly a wrong estimate. Notice that $\mathrm{L_0S}$ is the reciprocal of the square of a velocity, which is numerically equal to the ratio of the electromagnetic and electrostatic units, and is the velocity of light, or close to it.

It is clear that there is room for considerable improvement here in several ways, such as the establishment of the equations independently of such a very special hypothesis as Weber's; also in the estimation of L; and, in interpretation, to modernise it in accordance with Maxwell's ideas. Having observed that Maxwell, in his treatise, described the system (71*b*) of the last section, with no allowance for self-induction, and knowing this system to be quite inapplicable to short lines, I (in ignorance of Kirchhoff's investigation) made the necessary change of bringing in the electric force of inertia (*Phil. Mag.*, August, 1876), converting the system (71*b*) to the following:—

$$\left.\begin{aligned} -\frac{d\mathrm{V}}{dx} &= \mathrm{RC} + \mathrm{L}\frac{d\mathrm{C}}{dt}, \quad q = \mathrm{SV}, \\ -\frac{d\mathrm{C}}{dx} &= \frac{dq}{dt} = \mathrm{S}\frac{d\mathrm{V}}{dt}, \end{aligned}\right\} \quad \frac{d^2\mathrm{V}}{dx^2} = \mathrm{RS}\frac{d\mathrm{V}}{dt} + \mathrm{LS}\frac{d^2\mathrm{V}}{dt^2}, \quad (72b).$$

The equations on the left side show the elementary relations, and that on the right the resultant equation of V.

The difference from (71*b*) is only in the first equation of electric force, and in the characteristic equation of V. To the electric force due to V is added the electric force of inertia $-\mathrm{L}\dot{\mathrm{C}}$, where L is the inductance of the circuit per unit length, according to Maxwell's system of coefficients of electromagnetic induction. That is, L consists of three parts, say $\mathrm{L_0}$ for the dielectric, $\mathrm{L_1}$ for the wire, and $\mathrm{L_2}$ for the return. Their expressions will vary according to the size and shape of the conductors and their distance apart. In case of symmetry about an axis, their determination is very easy by the square of force method. The magnetic energy per unit length is $\frac{1}{2}\mathrm{LC}^2$. It is also $\Sigma\mu\mathrm{H}^2/8\pi$, if H is the magnetic force, and the summation extends over the region of space belonging to the unit length. As H is a simple function of C and of the distance from the axis, the integration is very easily effected.

L is calculated on the hypothesis that the current density has always the steady-flow distribution, just as R is the steady-flow resistance. As it is, strictly speaking, impossible to have the Faraday law of induction true in all parts of the conductors without some departure from the steady flow distributions, it is satisfactory to know that more exhaustive investigation shows that L, not $\mathrm{L_0}$, should be used in a first approximation.

In connection with this matter I may mention that rather singularly, just as I was investigating it, my brother, Mr. A. W. Heaviside, called my attention to certain effects observed on telegraph lines, which could be explained by the combined action of electrostatic and electromagnetic induction, causing electrical oscillations which made the pointers of the old alphabetical indicators jump several steps instead of one. When freed from practical complications, and worked down to the simplest form, the matter reduced to this, that the discharge of a condenser through a coil is of an oscillatory character, under certain circumstances, and I described the theory in the paper I have mentioned. It had been given by Sir W. Thomson in 1853, but it is a singular circumstance that this very remarkable and instructive phenomenon should not be so much as mentioned in the whole of Maxwell's treatise (first edition), though it is scarcely possible that he was unacquainted with it; if for no other reason, because it is so *simple* a deduction from his equations. I lay stress on the word simple, because it is not to be supposed that Maxwell was fully acquainted with the whole of the consequences of his important scheme.

Mr. Webb, the author of a suggestive little book on "Electrical Accumulation and Conduction," had very early practical experience of electrical oscillations in submarine cables, when they were coiled up on board ship, ceasing, more or less, as they were submerged.

It is far more difficult to obtain a satisfying mental representation of the electric force of inertia $-\mathrm{L}\dot{\mathrm{C}}$ than of that due to the potential, or $-d\mathrm{V}/dx$, as described in the last section. The water pipe analogy is, however, simple enough. Let L be the mass of the fluid per unit length, C its velocity, then $\frac{1}{2}\mathrm{LC}^2$ is its kinetic energy, LC its momentum, $\mathrm{L}\dot{\mathrm{C}}$ the force that must be applied to increase it, $-\mathrm{L}\dot{\mathrm{C}}$ the force of reaction. A mental representation of many of the phenomena connected with electrical oscillations is also very simply got by the use of the fluid analogy. It is, however, certainly wrong, as we find by carrying it out more fully into detail. Remark, however, that, as $\frac{1}{2}\mathrm{LC}^2$ is the magnetic energy per unit length, LC is the *generalised* momentum corresponding to C as a generalised velocity, $\mathrm{L}\dot{\mathrm{C}}$ the generalised externally applied force, an elec-

Digitized by Google

tric force, of course, and $-\mathrm{L}\dot{\mathrm{C}}$ the force of reaction—that is, the electric force of inertia. This is by the simple principles of dynamics, disconnected from any hypothesis as to the mechanism concerned.

The magnetic energy must be definitely localised in space, to the amount $\frac{1}{2}\mu\mathrm{H}^2/4\pi$ per unit volume, and be regarded as the kinetic energy of some kind of motion in the magnetic field. When steady, there is no force of inertia. But when H changes, and with it C, since these are rigidly connected (in our first approximation) there is necessarily a force of inertia, which, reckoned as an electric force appropriate to C as a generalised velocity, is $-\mathrm{L}\dot{\mathrm{C}}$ per unit length.

In the discharge of a condenser through a coil, if we start with a charge, but no current, there is in the first place only the potential energy of the displacement in the condenser. The discharge cannot take place without setting up a magnetic field, proportional in intensity to the current at any moment, so that the original electrical energy is employed in heating the wire, and also in setting up the magnetic energy. When the condenser is wholly discharged, the inertia of the magnetic field keeps the current going, and it will continue until the whole energy of the magnetic field is restored to the condenser (less the part wasted in the wire) in the form of the energy of the negative displacement there produced. Except that the charge is smaller, and of the opposite sign, everything is now as when we started, so that we may begin again and have a reverse current, continuing until the condenser is again charged in the same sense as at first, with no magnetic field. This is the course of a complete oscillation. But if the resistance be of or above a certain amount, depending on the capacity of the condenser and the inductance of the coil, the oscillations cease, and the discharge is completed in a single current which does not reverse itself.

Similar effects take place, in general, in any circuit, when a change is made which involves a redistribution of electric displacement, or its total discharge, but the full theory is usually very difficult to follow in detail. The so-called "false discharge" of a submarine cable is, however, easily comprehensible by the last paragraph.

If, in the characteristic equation of V in (72*b*), we take $\mathrm{L}=0$, reducing it to that of (71*b*), we have simple diffusion of the static charge. If, for instance, the ends of the line be insulated, any initial state of charge will settle down to be a uniform distribution, in a non-oscillatory manner, the smaller inequalities (smaller as regards length of line over which they extend) being wiped out rapidly, the larger more slowly; the law being that similar distributions subside similarly, but in times which are proportional to the squares of the lengths concerned.

If, on the other hand, we take $\mathrm{R}=0$ in the characteristic equation of V in (72*b*), we have an entirely different order of events. As there is no waste in the wire, it is clear that the total energy of any initial state, electric and magnetic, remains undiminished. We can definitely divide the initial state into two distinct states travelling in the manner of waves in opposite directions, and being continuously reflected at the ends. Or, more simply, set up a charge at a single point of the line. It will divide into two, which will go on travelling backwards and forwards for ever. But into details of this kind we must not be tempted to enter at present, the immediate object being to lay the foundations for a more general theory.

When both terms on the right side of the characteristic equation are counted, propagation takes place by a mixture of diffusion and wave transfer. A wave sent from one end of the line which would, were there no resistance, travel unchanged in form, and be reflected over and over again at the ends, in reality spreads out or diffuses itself, as well as, to a certain extent, being carried forward as a wave. The length of the line is an important factor. Wave characteristics get rapidly wiped out in the transmission of signals on a very long submarine cable, so that the manner of variation of the current at the distant end approximates to what it would be in the case of mere diffusion.

On the other hand, coming to a very short line, there are, every time a signal is made, immensely rapid dielectric oscillations, before the steady state is reached, due to to and fro reflection. As a general rule, this oscillatory phenomenon is unobservable, but it is none the less existent. It is customary to ignore it altogether in formulation, regarding the matter as one in which electromagnetic induction alone is concerned. Of course the magnetic energy is then far more important than the electric, and the current in the wire rises nearly in accordance with the electromagnetic theory.

The immense rapidity of the dielectric vibrations is one reason why they are unobservable, except indirectly, and under peculiar circumstances. Sometimes, however, they become prominent, especially when a circuit is suddenly interrupted, when we shall have large differences of potential. Mr. Edison discovered a new force. The enthusiasm displayed by his followers in investigating its properties was most edifying, and thoroughly characteristic of a vigorous and youthful nation. But it was only the dielectric oscillations, it is to be presumed; unless indeed it be really true, as has been reported, that the renowned inventor has kept the new force concealed on his person ever since.

How is it, it may be asked, that in the rise of the current in a short wire, according to the simple electromagnetic theory, the potential at any point in the wire is regarded as a constant, viz., its final value when the current has reached the steady state? Thus, as we have

$$\frac{e}{l}-\frac{d\mathrm{V}}{dx}=\mathrm{RC}+\mathrm{L}\frac{d\mathrm{C}}{dt}, \text{ and } \frac{d^2\mathrm{V}}{dx^2}=0,$$

if e is the total impressed force in the circuit, and l the length, the potential variation $d\mathrm{V}/dx$ must be constant. Supposing then e to exist only at $x=0$, the current will rise thus,

$$\mathrm{C}=\frac{e}{\mathrm{R}l}(1-\epsilon^{-\mathrm{R}t/\mathrm{L}}),$$

and the value of $-d\mathrm{V}/dx$ must be e/l, from the very moment e is started, and so long as it is kept on.

When we seek the interpretation, in the more general theory, we find that although the current oscillations become so insignificant on shortening the line that the well-known last formula becomes valid, practically, yet the potential oscillations remain in full force during the variable period. A wave of potential travels to and fro at the velocity $(\mathrm{LS})^{-\frac{1}{2}}$, making the potential at any one spot rapidly vibrate between a higher and a lower limit, though not according to the S. H. law, but in such a manner that its mean value is the final value, whilst the limits between which the vibration occurs continuously approach one another; the vibration, on the whole, subsiding according to the exponential law, with $2\mathrm{L}/\mathrm{R}$ as time constant. The quantity e/l, which in the above rudimentary theory is taken to be the actual potential variation, is really the mean value of the real rapidly vibrating potential variation, at every point of the circuit and during the whole variable period, at whose termination, on subsidence of the vibrations, it becomes the real potential variation.

To get rid of this vibration, we have merely to distribute the impressed force so as to do away with the potential variation.

Having now got the elementary relations established, we can proceed to the simplest manner of extending them to include the phenomena attending the propagation of current into the conductors from the dielectric.

(To be continued.)

Electric Light for Microscopic Projections.—Prof. Stricker in lecturing at Berlin before the Society of Natural History and of Medicine has employed with much success an arc lamp of 4,000 candle-power for the projection of microscopic sections upon a screen, employing a magnifying power of six to eight thousand diameters. Of course the success of an experiment of this character depends almost entirely upon the optical qualities of the apparatus, but in this instance it is stated that the definition obtained was so satisfactory that "important results in the progress of the study of anatomy" are anticipated from the further use of the electric light in this connection.

THE ELECTRICIAN.

TO CORRESPONDENTS.

All communications to be addressed to 1, Salisbury-court, Fleet-street, E.C. Those relating to Subscriptions, Advertisements, back numbers of the Paper, and so forth, should be addressed to the Publisher; and those relating to Articles, Correspondence, or Notes, to the Editor.

All letters intended for insertion in THE ELECTRICIAN, *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

SUBSCRIPTIONS.

THE ELECTRICIAN *can be had, by order, from any newsagent, in town or country, at the various railway stations; or it can, if preferred, be supplied direct from the office, on the following terms (paid in advance):—*

	3 months. s. d.	6 months. s. d.	12 months. s. d.
For United Kingdom	4 11	9 9	19 6
,, Foreign Parts and Colonies:— Within Postal Union	5 6	11 0	22 0
,, Labuan, Persia, Aden, Mozambique, Zanzibar, India, China, Japan, Borneo, Java, Philippine Islands, & New Caledonia	6 1	12 1	24 2

Cheques and P.O. Orders to be made payable to C. H. W. BIGGS.

Advertisements intended for the current week's issue must be handed in not later than Thursday, 4 p.m.

VOLUME XVII.

Volume XVII. of "The Electrician," price 10s. 6d., is now ready.

Also cases for binding, price 2s.

INDEX TO VOLUME XVII.

With our last number a Supplement was issued (Gratis), containing the Index to Vol. XVII. This Supplement should have been received with every copy of the paper. Complaints of non-receipt should be forwarded to the Publisher.

OURSELVES.

The first number of a new volume is a fitting and convenient place for any observations of a familar and personal kind which conductors of journals may at times desire to address to their readers; and in beginning to-day the eighteenth volume of *The Electrician* we avail ourselves of the privilege to offer a few remarks relating to the past career of our journal, together with some friendly suggestions as to its future prospects. As regards the past, we have much reason to be grateful to our helpers and supporters. Expressions of gratitude, however, would not count for much if we failed to show that we have deserved the help and support received; but seeing that these proofs of goodwill continue to be bestowed upon us, we may reasonably claim to have been not undeserving of them. When we say we, we mean, of course, *The Electrician*. Dr. Johnson tells us that when we run down self we do not mean our own selves in a literal sense; perhaps we may be permitted to observe on this that when a journal praises itself it only means it in a journalistic sense. As a journal *The Electrician* is able to look back with some pride on the work it has achieved for electrical science and electrical industry; and this largely by steady perseverance in a consistent course, which events are proving to be the right one; by sacrificing immediate popularity for an enduring reputation; and by subordinating pecuniary gain to the permanent interests it has undertaken to promote.

Turning to the practical details of our work, we have done all that the measure of our resources permitted to obtain the best authentic information of all scientific and industrial progress in the field of electrical enterprise. As our resources increased the quality of our matter and the finish of our illustrations have gone on improving. We confidently assert that in neither of these respects have we ever fallen below our contemporaries; and for a long time past they have frequently acknowledged our superiority—though not our identity—by reprinting our original matter as their own, which is, we suppose, the sincerest form of flattery journalism is capable of. Like all other newspapers we have to pay this kind of compliment at times, and we do it ungrudgingly; but, as a whole, our pages are occupied with original papers, no scientific journal with which we are acquainted having so largely invited and obtained the contributions of leading or rising members of the profession for its pages. The policy with regard to electric lighting constantly advocated in this journal, like its policy in relation to submarine cable laying, has sometimes been called in question; but in respect to the former, our aim has been to deprecate precipitate adventures, and in respect to the latter to protect existing interests against adventurers. Where genuine and legitimate work was to be done, we have helped it to the best of our power; where it was plainly speculative, or promoted merely out of rivalry, we have opposed it with all our might. The owners of submarine cables may or may not have cause to be grateful, but they have certainly no ground to deny the vigour and zeal with which their interests have been defended in the pages of this journal. The interests of electric lighting have been not less strenuously upheld by us; but, for reasons which need not now be recalled, it has sometimes been impossible to support the projects of particular undertakers in the interest of electric lighting as a whole. Naturally they are in a hurry to make money. For our part we are only anxious that the electric light should succeed, leaving the money-making to those it may concern later on. These remarks apply in like manner to the Telephone Companies, and the line we have pursued in regard to them.

As to the future, we have every reason to be sanguine that our list of contributors will go on enlarging and our number of subscribers increasing. But a journal of this kind has several difficulties to contend against, some of which are unavoidable, others which are easily remedied. The unavoidable are the multiplication of journals of all kinds, including those of a technical, industrial, and scientific kind. We do not fear their competition, but we do feel some apprehension lest the interests of the various industries related to electrical research may suffer from the diffusion and dilution of useful information to an extent which will practically prevent its reaching the eye and understanding of those for whom it is intended. If this should happen, it will be the fault of good natured scientists who out of personal regard or mere thoughtlessness generously

Digitized by Google

respond to any invitation to supply articles without due regard to the fitness of the place in which they will appear. No medical man ever dreams of writing on a medical question to any but the organ which represents his profession. Why physicists, chemists, and electricians should depart from this useful rule is more than we can explain. But they do, and one result is that if a reader interested in physical, chemical, or electrical subjects desires to keep himself fully informed, he must purchase, not one, but several expensive journals, any one or two of which ought to fully suffice. There may be room enough for the growth of new journals; but none of them would be the worse for minding its own peculiar business; and students would certainly be spared a great tax on their pockets and time if they knew where to go to seek what they want, and were certain to find it there.

Only on one other point do we wish to offer a word of remonstrance. We are often reproached with having neglected to notice this or that matter of interest in due time; and, on the other hand, it is hinted that where we do admit a notice we are advertising some favoured client. The actual fact is that, not being omniscient, we must to a large extent depend on notices personally furnished. To put it plainly, we favour those who favour us. People who forget that we are established to represent their interests and to make public their work must not be surprised if we occasionally forget them. What we want in this relation is information; if it is not furnished us, or means of obtaining it put in our way, obviously we cannot publish it. This is all the favour we have shown in the past, and all we ever mean to show in the future volumes of *The Electrician.*

INSURANCE AND ELECTRIC LIGHTING.

"The truth and nothing but the truth" is difficult to obtain, and in these days, when so many people fight for their own hand at all hazards, plain, straightforward honesty is at a discount. We are going to endeavour to give some unvarnished facts in connection with the subject mentioned at the head of this article. In the first place, recent criticism endeavours to fasten on to the insurance companies the odium of framing rules that tend to retard the progress of electric lighting. Now this is about as wide of the truth as any statement can possibly be. We prefer to think these critics are ignorant of the true state of the case rather than to imagine the statements deliberately made. Is it a fact that the insurance companies add nothing to their premiums on account of illuminants, except in certain particular cases where the risks are specially hazardous? If this is so—and we have reason to suspect the statement to be correct—then progress is not retarded by increase of premiums. But the critics say the premiums should be reduced when electric lighting is in question, for they hold strongly "it is so much less dangerous than gas." Facts are strange creatures, and facts tell us that outside of the work performed in accordance with insurance rules, the percentage of fires through electric lighting apparatus is larger than through gas apparatus. The reason of this will be seen below. Thus insurance companies, which have no reason for preferring gas to electric illuminants, object to the latter except under conditions of distribution laid down by them. We fail to see how progress is delayed by such action. Further, the insurance companies are said to be antagonistic to electric lighting, because they refuse risks where the work has not been carried out under their rules. We commend the companies for doing so, and our readers will do the same if they are honest in their endeavours to develop the industry in a proper manner.

We have been at some trouble to get at the facts; for the present we will content ourselves with mentioning one incident which occurred a few weeks ago. A letter was drafted by the officers of one of our largest companies, which it was intended to send to *The Times.* The draft letter was submitted to several other well known firms and companies. Without exception, we believe, all the experienced men to whom the letter was submitted agreed as to the truths stated therein; but on careful discussion it was deemed inexpedient to send the letter to *The Times,* or any other of the daily papers, simply because the publication of the letter would probably have led to such a scare amongst the non-technical public that the opposite effect to that intended would have happened, and the industry would have suffered. The text of the letter may be said to have been "bad workmanship." We have reason to know that previous to the letter being drafted, and during the discussion upon it, a number of examples of atrociously bad workmanship was before those who agreed with the terms of the letter. We have seen some of the specimens, and we have other and perhaps worse specimens that have not been shown to any person outside our own office. Coming back to the rules laid down by the insurance companies, it may be asked what is the plain duty of the companies in this matter? Are they not intended to protect the shareholders of the insurance companies from loss? Outside the question of loss, is it not the interest of the public to decrease the probability of fires, and to stop the possibility of putting in such materials and workmanship as will, in the opinion of any man but a born bigot, lead sooner or later to the total or partial destruction of the edifice? The Phœnix rules, for example, which apply to this country, were adopted after full discussion with, and in accordance with the opinions of, the best authorities engaged in the practical work of Electric Lighting. So far as we can gather, there has never been the slightest hesitation by the best known firms and companies in complying with the rules as laid down by the insurance companies. They are glad to follow the rules. Indeed, some practical men hold that the rules are not stringent enough. The men who criticise such rules adversely are generally men without experience, and usually are ashamed to make an attack in public, doing so under a *nom de plume,* so that no one can tell the value of the criticism. Another class of critics come from those who intend to make money, make it honestly if possible, but, at any rate, to make money. It is these men who take contracts at prices which cannot allow of good workmanship or good materials, and it is from such work that danger arises. Such men are the curse of the electrical as they are the curse of all industry. It is their action which retards the development of the industry, and upon them must fall the blame.

Those readers who are unable to credit our statements may ask, among others, such firms as Crompton and Co., Wilson Hartnell, Messrs. Verity and Sons, Messrs. Laing, Wharton, and Down, &c., and such companies as the Brush, Edison-Swan, Siemens Brothers, Woodhouse and Rawson, &c., their opinions concerning the action of the insurance companies in regard to bad workmanship. On the insurance side of the question Mr. Heaphy, who has had a good deal of experience in this matter, will be able to give his opinion. We invite such as are endeavouring to do good work to come forward, and once for all put upon record their conclusions upon this subject.

CORRESPONDENCE.

A NEW ACCUMULATOR CELL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 22nd October, page 484, you mention that a new accumulator cell has been brought out by M. P. Gudot, the principal feature of which appears to be in the "shape of the holes in which the active material is placed." You then describe them as having the "shape of truncated cones or pyramids, the plates being made up in pairs, with the widest sides of the holes in juxtaposition."

Might I call your attention to a patent specification (A.D. 1885, 14th July, No. 8540), in which an inventor claims a "voltaic battery having for negative elements plates of lead perforated with tapering holes, filled with oxide of lead and fixed together in pairs?"—Yours, &c.,

WM. C. FISHER.

17, Cornhill, E.C., November 4th, 1886.

THE JARMAN ELECTRICAL TRAMCAR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think a few corrections are necessary in your note upon my model electric tramcar, published in *The Electrician* of October 29th.

1st. The model is 4ft. 7in. long, and not 2ft. as you state.

2nd. I do claim a special feature in the construction of the electro-motor, by affixing two armatures upon a shaft or spindle for the purposes claimed, *no* clutch being employed.

3rd. Spur gearing is used but *no* mitre wheels. This latter plan is a sad mistake, as many will have cause to know in all probability. The gearing designed for the model answers perfectly. I am quite acquainted with the effect of passing a heavy current through an electro-motor for the above purpose, having had sufficient experience in this direction to lead me to the present design. When a copper conductor can be made to carry a current five or six times more than it will safely bear, *then* armatures will be made that will not heat. I have taken this excessive heating of the electro-motor as it stands, and as far as tests have gone they bear out exactly what was designed. As far as the teeth of the gearing are concerned, there is another material I intend to employ which is superior to hornbeam.

There is another important feature in my present design for electrically propelled cars which has been entirely overlooked, a feature that every electrically propelled car *must* possess before it will be permitted for general use. I hope to point this out when the full size car is completed.—Yours, &c.,

82, Kellett-road, Brixton, Nov. 6th, 1886. A. J. JARMAN.

[If Mr. Jarman will refer again to the note in which we mentioned his tramcar, he will perceive that our reference to the heating of the armatures of series-wound motors on starting the current was mentioned as a point—in fact, the *chief* point—to be considered in favour of his system.—ED. *E.*].

THE LAW OF THE SQUARES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Since the time of Coulomb, all the manuals have glibly repeated the law that electric and magnetic forces decrease as the square of the distance, and I now have before me a paper read before the British Association, with a discussion thereon, upon the celebrated Cavendish proof of that law. For the life of me I cannot obtain from all the display the ghost of an idea of its validity. If Lord Rayleigh, or some of his eminent and esteemed compeers, would condescend to translate this high shibboleth into a brief paraphrase, reduced to the level of a common understanding, it might be appreciated by a very wide audience. If it only means that these forces decrease as the law of the squares, *under radiant conditions*, it goes for very little, because under ordinary circumstances such conditions seldom or never subsist.

Given a uniform field of force, as between the plates of a condenser, and *we know* that these forces decrease *directly* as the distance apart; a double thickness of dielectric gives a double resistance, or half the inductive effect, and for round surfaces, as in the case of insulated wires, *we know* that the law of decrease is well established by the logarithm of the ratio between the inner and outer circumference of the dielectric.

But this does not approximate the law of the squares, as in departing from flat surfaces it varies in an opposite direction.

It is not an easy matter to obtain a strictly uniform field of magnetic lines of force; but in proportion as that is attained must the same law of decrease with distance prevail, as between the plates of a condenser.

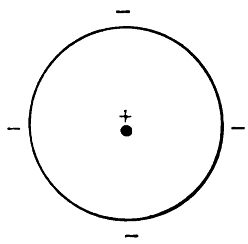
Let us now test a straight bar magnet, and the lines of force may vary in many ways according to the character and shape of the body presented and to the relative nature of the medium involved; but in a wide sense we may say that for a very limited space beyond the pole the force decreases *directly* as the distance, and rapidly varies until we pass a region where the law of the squares must be approximated, beyond which the rate increases far beyond that ratio, until from the curvature of the lines to the opposite pole we get approximately no force at all.

Is it, then, right to say of this force, as a whole, that it decreases as the square of the distance?

May we not go farther in this direction, and say that there is nothing in the nature of light or sound vibrations *per se*, which determines their decrease as the law of the squares? The feeble sounds heard through a stethescope do not so decrease, nor do the rays of light transmitted through a telescope; but in both light and sound there is no duality of force to modify or prevent the usual conditions of true radiation.

In the Cavendish experiment I presume we have a small charged sphere, in the centre of a bare room, with lines of force radiating to the walls, floor, and ceiling, where the opposite charge necessarily subsists. This is probably a sufficient approximation for the purpose in view; but for absolutely true radiation, methinks that the opposite charge should be on a circular circumference, equally distant at all points from the central force.

In like manner the Coulomb experiment is very much of the same character, which may perhaps be better understood by a rough diagrammatic representation. In this case we may



imagine a small metallised pith-ball, charged at the centre, and the opposite charge necessarily resident upon the surrounding surface of the electrometer. If we now imagine another similar ball, near the outside, it would be inductively affected, and would be attracted to the centre with a force *increasing* as the square of the distance up to actual contact. We may now vary this according to the actual conditions of the Coulomb experiments, and whether we charge the two balls similarly for repulsion or oppositely for attraction, the general effects will be substantially similar. The balls are small spheres, and the forces are virtually resident at their centres, and in any case the conditions are roughly approximative of radiation. It is common to speak of the forces as resident in the two balls, but the effect is really due to an action of the lines of force in the dielectric air.

We may now go back to the Cavendish room, and vary the experiment in two ways: 1st. With the charged sphere, near to one of the walls of the room; and 2nd, with a lighted candle in its place. In the latter case the radiation would be perfect, and decrease according to the law

Digitized by Google

of the squares would be as truly evinced towards the nearest corner as to one the most distant. But not so with the sphere; its force would be chiefly accumulated towards the nearest surface, where it would approximate the law of flat surfaces, and the distant parts would be correspondingly denuded of the influence.

Let it be understood that these thoughts are offered in an inquiring spirit rather than in a dogmatic sense.—Yours, &c.,

SAM. E. PHILLIPS, F.C.S.

LITERATURE.

Short Lectures to Electrical Artizans. By J. A. FLEMING, M.A., D.Sc. [London: E. and F. N. Spon.]

This book is a transcript of a course of experimental lectures delivered to a practical audience. We think the author is quite justified in seeking, by publication, a larger audience for these lectures than that which originally listened to them in the works of Messrs. Crompton and Co. It was an admirable step on the part of Mr. Crompton to arrange for the delivery of these lectures to the pupils and workmen connected with his firm; but the arrangement could not have been an easy one for the lecturer, who must have felt that he would have much preferred an audience of a more homogeneous character. Unfortunately, in spite of all the mechanics' institutes and similar places established for the benefit of working men, it must be confessed that the average English craftsman is not sufficiently alive to the benefit which must result from technical and scientific studies bearing on the branch of the manufacturing industry in which he may be engaged. Mr. Crompton was no doubt aware of this when he requested Dr. Fleming to deliver his lectures, and he probably took the best means in his power to benefit his men by placing before them information of which, if they are like the majority of working men, they would not of their own accord have gone in search. We feel that there may be many amongst our readers, in these days of the apotheosis of the British workman, who will object to our remarks that they are unjust. We wish we could believe this to be the case. We know it is not, and that in many so-called "Mechanics' Institutes" there is hardly a mechanic on the roll of members. It is a fact to be regretted, but it is one which nobody who has worked much in connection with such institutions will deny, that the efforts which have so long been made to reach working men succeed only in a very partial degree. They reach, not the actual mechanics and craftsmen, but a class a step or two higher in the social scale. The author has done his best under the circumstances.

The lectures, as might have been expected, are a little above the average workman, and are just enough to refresh the memories of the pupils who, we presume, were learning to apply practically the scientific knowledge which they had gained at technical schools and colleges. This is not faint praise. The book is an excellent one in its way, and as "introductory to larger treatises," as the author puts it in his preface, is all that can be desired. That one part of his audience were, or should have been, already acquainted with the larger treatises, and that the other part were probably for the most part ignorant of even the elements of scientific knowledge of their work was the misfortune and not the fault of the lecturer.

But we think this book fills a distinct void in electrical literature. It is a great relief to read it after having, by a hard fate, been obliged to examine numerous well-meant but imperfect attempts to impart knowledge of modern electrical development in the form which is known, by an abuse of terms, as "popular" scientific literature; for the book, although a little unequal, is clear, exact, and to the point, and is characterised by an evident—and successful—desire to enable distinct and unclouded conceptions to be formed of the various laws and phenomena dealt with. It is in very good taste, too, that there is no prominence given to the manufacture or methods of any one firm or constructor.

The information is brought up to date—a thing hitherto undreamt of by any "popular" writer. For instance, Dr. Hopkinson's method of testing the efficiency of a dynamo and motor is fully given; and Mr. Shelford Bidwell's recent investigations on the magnetisation of iron are fully described in an appendix. We are glad to notice (page 122, Fig. 50) a description of the excellent apparatus for showing the analogy between fall of pressure in hydraulics and fall of potential in electricity. We do not remember to have seen this simple apparatus described in any text book on electricity. It is a simple though a most instructive one; but we would suggest that the author should place in the horizontal pipe a piece of rubber tube capable of constriction, for the purpose of demonstrating the difference of potential produced by the insertion of "a resistance" in a circuit. We notice several old friends amongst the engravings, but they are all welcome ones, notably the plate from M. Kapp's book, showing the various forms of field-magnet of dynamos and the views of lines of force from the same source.

Perhaps too much space is given to measuring instruments, for although science may be measurement, measuring instruments are perhaps not the direction in which the most satisfactory progress has been made in electric light matters. We trust that in a future edition Dr. Fleming will add considerably to his index. In conclusion, we unhesitatingly recommend this little work to those amongst our readers who wish to place in the hands of their friends an introduction to the science of practical electrical engineering.

M. MARCEL DEPREZ ON THE MAGNETIC CIRCUIT.

On the 26th October a paper was presented to the *Academie des Sciences*, by M. Marcel Deprez, upon the intensity of the magnetic field in dynamo machines, of which the following is an abstract. We may remark in advance that M. Deprez's views are not in accord with the theory which has just received so remarkable a vindication at the hands of Mr. Kapp in the paper which was read last night at the Society of Telegraph-Engineers, "On the Predetermination of the Characteristics of a Dynamo." We should like to ask M. Deprez whether the views which he puts forward enable him also to determine beforehand the performance of a machine built to a given specification. If the theory will stand this test the position will become one of decided interest.

M. Deprez commences by stating that he has undertaken a long series of experiments in order to determine the influence of the shape and dimensions of the air space upon the intensity of the magnetic field. The intensity of the field was inferred from the measurement of the force exerted upon a movable conductor traversed by a continuous current. The first conclusion arrived at was that "contrary to what certain electricians have affirmed, *the intensity of the field decreases much less rapidly than the distance between the poles increases.*" For instance with two horse-shoe electro-magnets having cores 200mm. in diameter, the intensity of the field was reduced only one half, when the distance between the poles was increased from 7·5mm. to 75mm.—that is ten-fold.

"When the field is comprised between a magnetic pole and an iron armature, magnetised by its influence, the decrease of the intensity, corresponding to the increase of the distance, is more rapid; but it is still very far from what was once supposed, since, instead of being proportional to the square of the distance of the magnetic pieces in question, as it has been affirmed by certain persons led by a crude analogy, it is superior even to the inverse of the square root of the distance. To render this more clear, when the distance increases from 1 to 4 the intensity of the field falls from 1 to 0·6.

"In all cases the larger the cores of the electro-magnets, the more considerable is the current which excites them; the thicker the armatures upon which they act, the less is the influence of the distance from the armature to the poles of the electro-magnet. *Hence it follows that on bringing the armatures of the inducing poles very close, we increase the intensity of*

Digitized by Google

the field very little, whilst we reduce the place available for the induced wire almost to zero.

"If in a dynamo machine we vary the annular space compri ed between the polar expansions and the outer surface of the iron core of the ring as well as the quantity of induced wire coiled upon the latter, so as to fill the annular space as completely as possible without interfering with the free action of the machine, it is certain that the efficacy of the machine will vary with the dimension of the annular space; it will be null when this dimension is very small, because the insulating materials which surround the iron ring, as well as the clearance which must exist between it and the fixed polar pieces, will absorb all the available space, and leave no place where the induced wire may be introduced. It will be, if not null, at least very feeble, if we give an excessive dimension to the annular space. There exists, therefore, a dimension of this annular space corresponding to the greatest possible efficiency of the machine. But before searching for the most favourable dimension we must define this efficiency. If we determine all the dimensions of the machine (except the annular space) its speed of rotation and the electromotive force which it should produce, I will say that its efficiency is greatest when the internal resistance of the ring is at a minimum.

"If we call x the dimension of the annular space taken in the direction of the radius of the ring; a, the minimum value of the space allowed for the insulating matters which cover the iron core, for the clearance indispensable to the free working of the parts, and, in a word, for all matter *other than the copper* conductor of the current coiled around the induced ring, such space being likewise taken in the direction of the radius, and H the intensity of the field, it can easily be shown that the internal resistance of the machine is a minimum when the function $H^2(x-a)$ is a maximum.

"The experiments referred to above show that this maximum occurs for values of x much greater than is commonly supposed. These results, moreover, merely confirm those which I obtained about eighteen months ago with Gramme machines, in which I diminished the annular space more and more. The intensity of the magnetic field increased beyond doubt, but the machine became very decidedly worse as the annular space became smaller.

"In machines of high tension, such as those which I had constructed for the experiments at Creil, the value of the constant a is much greater than in machines of a low tension, because they require a far more perfect insulation.

"Hence it results that the function $H^2(x-a)$ reaches its maximum only for values of x very much greater than if a were small. This is the reason why I have been obliged to give the annular space so great a value in the Creil machines. This will readily appear if we know that the distance from the outer part of the induced wire to the polar pieces reaches in places 0·01 metre, and that the thickness of the insulating layer interposed between the iron core and the first layer of the induced wire was 0 0075 metre. This then made a space of 0 0175 metre entirely lost for the useful effect of the machine, so that if I had only given to the annular interval 0 020 metre, there would remain for the induced wire merely 0·0025 metre, that is to say, room enough to lodge a single layer of wire, the machine would not have yielded the eighth part of the electromotive force required.

"I have made a few experiments upon the influence of the dimensions perpendicular to the lines of force, and I have been able to ascertain that unless the polar pieces are very thick in the direction of the lines of force the intensity of the field is approximately in the inverse ratio of the developed surface of the polar expansions taken perpendicularly to the lines of force.

"With electro-magnets, the core of which was 200 millimetres in diameter, the magnetic field comprised between the poles has reached the value of 15,400 C.G.S. units, when the polar pieces of a square form measured 200 millimetres per side and were 3 millimetres apart; it was still 11,400 units when the distance was 20 millimetres. The electric work expended collectively in the helices of the two electro-magnets amounted to 9 horse-power."

BRITISH ASSOCIATION, 1886.

One of the most important innovations introduced at the meetings of the British Association in 1885 led to the admirable paper of Prof. Lodge on "Electrolysis." This paper was supplemented at the 1886 meeting, recently held, by a series of short papers on special points in electrolytic theory, which we commence to give herewith:—

ON CONDUCTIVITY OF VERY DILUTE SOLUTIONS.*

BY DR. F. KOHLRAUSCH.

This memoir is an extension of previous work, and was undertaken for the purpose of verifying the following laws laid down by Kohlrausch in a former paper:—

1. If dilute solutions of various salts be prepared, having their strengths proportional to the chemical equivalents of the salts, then the specific conductivities of these solutions are of the same order of magnitude.

2. In dilute solutions, under a given electromotive force, each of the ions moves through the liquid with a fixed velocity dependent on its own chemical nature, and independent of that of the other ion. This is termed the "law of independent migration."

3. The influence of change in temperature upon the conductivity tends, as dilution increases, to a limiting value, the temperature coefficient being the same, within narrow limits, for all neutral salts.

In his previous investigations Kohlrausch had determined the specific conductivities of solutions of varying strength, from saturation down to a few per cents, and from observations thus obtained had deduced the conductivity in more dilute solutions by extrapolation. In the present memoir he verifies and corrects the results thus obtained by the employment of solutions whose strengths vary from 1·0 to 0·00001 gramme-equivalents per litre. (The strength thus estimated is termed the "molecular content.")

In measuring the resistances a Wheatstone bridge is used, with alternating currents and a telephone as indicator (the paper deals at some length with the advantages and difficulties of this method); the specific conductivities are expressed in terms of that of mercury, and calculated for a uniform temperature of 18° C.

In working up the results the conception of "specific molecular conductivity" is employed, this being defined as the ratio k/m of the specific conductivity k of the solution to the molecular content m. As the specific molecular conductivities are all very small, Kohlrausch tabulates the values of $10^8 . k/m$, instead of k/m simply. The values of this ratio are exhibited graphically, by plotting in a curve, with $m^{\frac{1}{3}}$ as abscissa, this quantity being chosen because it expresses "the reciprocal of the mean [distance," or, in other words, the *mean relative proximity* of the molecules—*i.e.*, the magnitude on which the specific molecular conductivity is most directly dependent.

The material thus obtained is amply sufficient to verify the three statements above mentioned, the very important law of independent migration in particular receiving a full confirmation. In addition a large number of interesting relations disclosed themselves, which may be summarised as follows:—

1. If the solution be sufficiently dilute the specific molecular conductivity k/m is, for all neutral salts, independent of the strength of the solution, or each molecule conducts the current independently of every other. In other words, the specific molecular conductor has a limiting value. These limiting values are not the same for all salts, or even for those of the same base or acid; their magnitude depends on the nature of both ions.

2. The velocity with which the ions move past each other in extremely dilute solution, under an electromotive force of 1 volt per linear millimetre, is determined in millimetres per second by multiplying the specific molecular conductivity of the electrolyte by 11000† (or Kohlrausch's tabulated numbers

* Abstract of F. Kohlrausch's Paper "*Ueber das Leitungsvermögen einiger Electrolyte in äusserst verdünnter wässeriger Lösung*" (*Wied. Ann.* XXXVI. p. 161).—Drawn up by E. F. J. Love, and communicated to the British Association at Birmingham.

† [This appears to be necessary in order to reduce measures in terms of mercury to absolute measure.—E. F. J. L.]

Digitized by Google

by 0·00011). The numbers thus obtained for the various salts examined all lie between 0·14 and 0·10 *mm/sec.*

3. The specific molecular conductivity of a salt in dilute solution being proportional to the sum of the velocities of the separated ions, the values of these absolute velocities may, as Kohlrausch had shown previously, be determined from the experiments in the following way:—

Let u_1 and v_1 be the absolute velocities of K and Cl, u_2 and v_2 those of Na and Br; then the

Specific molecular conductivity, k/m, of $KCl = (u_1 + v_1)/11000$
" " " " $NaCl = (u_2 + v_1)/11000$

and so on; hence the conductivities of KCl, NaCl, KBr, and NaBr, contain all that is necessary for determining the absolute velocities of K, Na, Cl, and Br; since by the law of independent migration the velocity of Br, for instance, is the same in KBr as in NaBr.

Employing numbers thus determined Kohlrausch has calculated the specific conductivities of a number of salts in dilute solution; and the calculated and observed values show a satisfactory agreement.

4. As the strength of the solution increases the specific molecular conductivity slowly diminishes. It may be approximately represented by the formula

$$k/m = A - Bm^{-\frac{1}{3}}$$

aud since $m^{-\frac{1}{3}}$ = the relative mean distance r of the molecules,

$$k/m = A - B/r,$$

or "the specific molecular conductivity is equal to a constant diminished by a quantity inversely proportional to the mean distance of the molecules."

5. The rate of diminution of k/m with increasing concentration is greater the higher the valency of the ions. This is ascribed to two possible causes—(*a*) a change in the constitution of the polyvalent ion, in virtue of which it approximates in behaviour to a monovalent ion, as the dilution increases; (*b*) the possibility that the current may be in part conveyed by the water of the solution.

6. The specific conductivity of a salt appears to be unaffected by its possessing, or being destitute of, water of crystallisation.

The above conclusions refer only to neutral salts; acids and alkalis (including alkaline carbonates) behave in a different manner. The chief facts collected by the author regarding these substances are—

1. The specific molecular conductivity of acids and alkalies is small if the dilution be very great, increases with the strength of the solution up to a certain maximum, and from this point diminishes as the concentration increases. The small initial value of k/m he considers (following Arrhenius and Ostwald) to be a secondary phenomenon—probably due to impurities in the water—and accordingly he neglects this part of the curve, and obtains the limiting value of the specific molecular conductivity by producing the second part backwards through the maximum to the line of ordinates. He thus obtains as the maximum limiting velocity of the ions 0·4 *mm/sec*, under and electromotive force of 1 volt per linear millimetre.

2. The alkalies KOH and NaOH have specific molecular conductivities differing by a small constant amount, as also have their carbonates.

3. The monobasic mineral acids have the same specific molecular conductivity. Phosphoric acid gives a nearly identical value if, instead of the equivalent $\frac{1}{3}H_3PO_4$, we employ the whole molecule H_3PO_4.

4. Acetic acid and ammonia in dilute solution exhibit a specific molecular conductivity nearly proportional to $m^{-\frac{1}{2}}$. In strong solution they conduct very badly.

5. Sulphuric acid is anomalous, exhibiting three maxima and two minima. The first minimum corresponds to the hydrate $H_2SO_4.H_2O$, and the second to concentrated H_2SO_4. One of the maxima occurs between this point and SO_3. This behaviour points to a chemical change in the structure of the molecule depending on the concentration.

With regard to the problem of electrolytic conduction in general, Kohlrausch lays down the axiom that no electrolyte in a pure state is a good conductor, but only becomes such on admixture with other bodies, this admixture being necessary in order to set up the dissociation which Clausius looks upon as the cause of migration of the ions. In this connection the question is discussed as to whether the water of a solution conducts part of the current. This our author considers extremely likely, as such a circumstance would explain various anomalies.

Kohlrausch discusses Bouty's "law of equivalents," which states that "the electric conductivity of dilute salt-solutions of equivalent strengths is the same for different substances." Bouty distinguishes between "normal" salts, which obey the law, and abnormal salts, which do not; and defines an abnormal salt as one "whose constituent ions in dilute solution travel with different velocities." But Kohlrausch shows that some salts which would come under this definition obey Bouty's law, while some of the salts which disagree with it can be shown to be "normal," from observations on their migration-constants. He also objects to the law on the ground of its inherent improbability, and alleges further that Bouty's method of calculation is erroneous. The cases, therefore, of agreement with the law he looks on as coincidences.

Among minor points of interest brought out by the investigation are the following:—

1. The low conducting power of nearly pure water, the smallest value obtained being $0·25 \times 10^{-10}$.

2. The phenomenon of absorption by the electrodes. The conductivity of a very dilute solution of HCl was found to slowly diminish owing to the withdrawal of the acid from the solution. That this is due to the electrodes was shown by an increase in the resistance on sinking them in the fluid, the higher conductivity being restored by stirring. The phenomenon is not exhibited by solutions of neutral salts.

3. The specific molecular conductivity of a strong base or acid is diminished by gradual neutralisation, reaches a strongly defined minimum when neutralisation is complete, and thence increases. Phosphoric acid shows several such minima; acetic acid gives a curve of *gradually* changing curvature, the neutralisation point being apparently somewhat indefinite.

ON CONTINUITY OF ELECTRIC CONDUCTION.*

BY DR. HOPKINSON.

In my experiments on residual charge I touched upon the second question in Lodge's programme ("Is Ohm's law obeyed by very bad conductors?")†, and pointed out that Ohm's law could be regarded as a limiting case of a more general law of superposition. In the case of mechanical after-effects the law of superposition does not hold, even approximately. The fourth question ("Is there any relation between optical opacity and electrolytic conductivity?") appears to me to be very intimately associated with the fact that bodies which, if they conducted, would be electrolysed do not follow Maxwell's law, whereas some other insulators do. My own present impression is that an electrical displacement in glass may, although continuous, be roughly divided into four successive stages. 1st. A yielding of the dielectric during a time corresponding to the time of wave frequency of light, for which $K = 2\frac{1}{2}$ about. 2nd. A further yielding during a time corresponding to great absorption below the red, bringing K up to from 6 to 10. 3rd. A further slow yielding, partly recoverable, hardly sensible in time less than a second or such like, and going on with diminishing amount for days. 4th. A yielding corresponding to an actual decomposition of the material. Superposition probably applies to all these continuously connected successive events. Probably if we could experiment fast enough on any ordinary electrolyte, like solution of $CuSO_4$, we should find a similar succession of phenomena.

[Dr. Hopkinson's note is of extreme interest, and the references to his papers are as follows:—"Residual Charge in Leyden Jar," *Phil. Trans.*, January 1877; "Strain in Glass Fibre," *Proc.* Royal Society," October 4, 1878; "Refractive Index and Specific Inductive Capacity, *Phil. Mag.*, April 1882. This last paper I may abstract thus:—

Maxwell's laws are that $\mu^2 = K$, and that transparent bodies

* Communication to the British Association Committee on Electrolysis.
† A programme of suggestions issued to the British Association Committee on Electrolysis.

Digitized by Google

must insulate. They are true for mineral oils and solid paraffin; not true for glass, Iceland spar, and organic oils. Consider, for instance, light flint glass: K is 6·7 for disturbances whose period is longer than 10^{-5} second, and for these disturbances it behaves as an insulator. It ought, therefore, for such waves to be transparent, and to have an index 2·6. But, for disturbances of period about 10^{-15} second, its index, reckoned for very long waves by extrapolation formula, comes out about 1·5. Is there any way of accounting for this discrepancy? Yes; perhaps by the known fact that on waves *between* these two periods glass exercises a strong selective absorption, and that this is usually accompanied by anomalous dispersion, which at once renders all empirical reasoning towards the state of things for very long waves, from the observed condition for very short waves, utterly futile and misleading. Perhaps, therefore, Maxwell's law is after all obeyed by these substances for long waves, and one way to test the question is by using rays from a thermopile to a freezing mixture.

O. L.]

ON THE ELECTRIC RESISTANCE OF MAGNETITE.

BY PROF. SILVANUS P. THOMPSON, D.SC.

This is a preliminary note on a research begun with the view of elucidating the question whether the conduction exhibited by various mineral ores and metallic oxides and sulphides possessing quasi-metallic conductivity is or is not accompanied by electrolysis. The substance selected, magnetite or magnetic iron ore, is a thoroughly good conductor, as is evidenced by the simple fact that if a piece of it be interposed in the circuit of an ordinary electric bell the bell can be rung through it.

The sample selected was a fine homogeneous piece of ore from Arkansas, and was reduced by the lapidary's wheel to parallelipipedal bar. Its total length was 5·53 centimetres, its breadth 1·52 centimetre, and its thickness 1·27 centimetre.

The bar was placed between electrodes of platinum foil, which were clamped against its end-faces by means of screws; it was then placed in a bath of paraffin oil, enabling it to be heated to any desired temperature up to 135° C.

To test for electrolytic polarisation a current of about 1 ampere was passed through it from three nitric acid cells for some minutes. On stopping the current there appeared a slight polarisation, not, however, exceeding 0·0005 volt, and therefore of an order indicating a thermo-electric rather than an electro-chemical origin.

The specific resistance was then measured by observing the fall of potential between two marked points 3·22 centimetres apart upon the bar, and comparing this with the fall of potential between the two ends of a standard resistance coil, intercalated in the same circuit. The resistance was found to diminish very remarkably as the temperature was raised. Observations were made at intervals of from twenty to forty minutes apart, with the following result:—

Temperature (C.)	Resist. of centimetre cube in B.A. units.
23°	0·719
54°	·709
79·5°	·505
107°	·416
133°	·287

It appears that the resistance of magnetite agrees with that of carbon and the electrolytes in possessing a negative temperature coefficient.

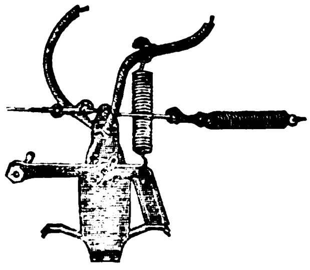
A somewhat longer and thinner bar of hæmatite prepared for future experiments showed a resistance of about 108 megohms, which in a preliminary heating fell to 81 megohms.

The determinations were made by the author's chief assistant, Dr. R. M. Walmsley.

ELECTRIC "CONDUIT" TRAM LINES.

By the term "conduit" tram lines we may distinguish that system in which current is supplied to the electric motor by means of a trailing collector, running upon an insulated cable placed in an open conduit, which is sunk in the centre of the line. For electric street tramways this is the only system which promises to be able to compete with the use of secondary batteries. Mr. Holroyd Smith is, as is well known, the chief exponent of this system, and, so far as we are aware, with the exception of the Blackpool line, there is only one other example of the system at present in operation. This is to be found in a line at Philadelphia, which has been constructed by Mr. Schlesinger. At the meeting of the Franklin Institute, on October 20th, the details of this line were described at length. It appears, however, that of the three points of chief interest, namely, the method of regulation, and the construction of the conduit and of the collector, only the latter has at present received a final solution, the two former being avowedly of a temporary character. Nevertheless, the line is running very successfully, though only one car is at present at work. The form of collector which experience has shown to be most suitable is shown in the accompanying figure.

It should first be stated that Mr. Schlesinger does not employ the rails as a return, but prefers to use two insulated copper cables—or, rather, strips—both of which are placed in the same conduit. The collector consists of a cast-iron frame, which carries a strong finger to remove obstructions from the slot. This frame is secured by means of a bolt to the car, in such a manner as to allow it perfectly free motion in a vertical and sufficient in a horizontal plane. Through a fork in the frame a phosphor-bronze casting passes, fastened to it by means of a bolt, so as to swing freely in a vertical plane and to have enough side-play. This casting passes into the slot, and carries two steel springs well insulated from it and from each other. A strong spiral spring, which takes up all the irregularities in the motion of the car, presses the springs against the conductors. To furthermore insure good conduct, the phosphor-bronze casting is connected by springs and wire ropes to a lever on the front platform. With this lever the casting is



The Collector.

tilted in such a manner that in going forward the front parts of the contact-springs, and in going backward the back parts are moved away from the conductors. Two such collectors are supplied to each car, one having the cast-iron finger pointing forwards, the other backwards. The connection between the contact springs and the motor on the car is made by means of well-insulated wires, protected where they pass through the slot by steel plates riveted to the phosphor-bronze frame.

The E.M.F. employed is somewhat low for this class of work, being only 160 volts; the current on the level is between 15 and 17 amperes; on an incline of 1 in 30 this increases to 45 amperes. The empty car weighs 7,100lb., and it carries forty-five passengers, which probably brings the total weight, when fully loaded up, to about 6 tons.

DUPLEX TELEPHONE CIRCUITS.

The telephone lines connecting New York and Philadelphia have recently been duplexed by a method due to Mr. J. Barrett, of Brooklyn. The duplexing of telephone circuits has already been accomplished in America upon a method the principle of which consists in the use of a metallic circuit in combination with an earth circuit. One set of instruments is worked upon the metallic circuit in the ordinary manner, and the two wires form a common line with respect to the earth circuit in which the other set of instruments is placed, suitable resistances being inserted to maintain a balance in each circuit.

There are certain difficulties encountered in this method of operating, which consist in the fact that a considerable portion

Digitized by Google

of the energy of the current traversing the circuit is dissipated in overcoming the balancing resistances, and the current is necessarily so subdivided that its action upon the receiving magnets is of a very limited nature.

The following description of the method now adopted on the New York and Philadelphia Line is taken from the *Electrical World* of New York:—Mr. Barrett's system, broadly stated, consists in bringing the metallic or double wire instruments at the terminal stations into inductive relation by means of converting or repeating induction-coils with both sides of the circuit, instead of connecting them directly with that circuit by means of a bridge-wire. The currents traversing the metallic circuit are thus economised, inasmuch as they are only required to traverse a direct circuit, while the accompanying currents, which are initiated in the earth branch at either terminal station to actuate the corresponding receiving instrument in the distant earth branch, cannot affect the intermediate double-wire instruments, as the current generated by the earth-branch transmitters at any given instant acts upon both sides of the double-wire receivers alike, the current induced in one converting coil being opposite in direction to that induced in the other at the same instant, so that its effect is thus neutralised by its own action.

Mr. Barrett provides a double-wire line circuit, and at the terminal stations includes in each wire of the circuit an induction coil wound with two insulated wires side by side, one of which wires is directly in circuit with the double wire line, while the other is connected in circuit with the secondary helix of a telephone transmitter and with the coil of a telephone receiver. Thus messages from a distant station reach the receiver by means of induction through the converting coils, one of which is in the direct and the other in the return wire, while messages spoken in the transmitter develop currents in the secondary circuit of its induction coil, and these again by induction develop tertiary currents of coincident direction with one another in both converting coils simultaneously, which currents, being of like direction, re-enforce one another and travese the line to act through like converters upon the distant receiver. To a point of the metallic circuit at each terminal station, equidistant from the converting coils, an earth branch is attached, including the usual telephone instruments. Telephonic currents developed in the transmitters at either terminal station in the earth branches will traverse both direct and return wire in the same direction; that is, in relation to any intermediate point or appliance the current in both lines will be at any given moment positive or negative; hence, while the receiving telephone in the distant earth branch will readily respond to their action the intermediate instruments will be totally irresponsive, for the reasons stated above.

In the accompanying diagram of circuits, Fig. 1 represents the plan adopted of inductively connecting the metallic circuit instruments primarily. As will be seen, there are at each station two converting induction coils, 1 and 2, the two insulating wires of which, of identical gauge and length, are wound together, so that each conductor is in close inductive proximity to the other throughout its entire length. One of the conductors, 3, of the converting coils is included at each station, as shown, in the circuit of the direct wires w and w', so that the conductors of each coil are virtually placed in direct circuit serially with the line. The other conducting wires 4 of the coils are joined up in a local or home circuit comprising the receiving or magneto telephone t and the secondary helix of the transmitting telephone induction coil T, the latter being operated in the usual manner through the intermediation of the primary helix by the transmitter 7 and battery 8. The local circuit may be traced as follows:—Wire 4 of converting coil 1, secondary transmitter coil T, receiving telephone t, wire 4 of converting coil 2, and thence by conductor w^2 back to the starting point. The route of the main circuit in like manner may be traced from an arbitrary starting point, z, at station A, through wire 3 of converting coil 2, line wire w, through the converting coils 1 and 2 at station B, and back *viâ* line wire w' and through coil 1 at station A, back to the point z. Each converting coil is provided with a soft iron magnetic core, which is adjustable with respect to the extent of its insertion in the helix spool, for a purpose which will be described below.

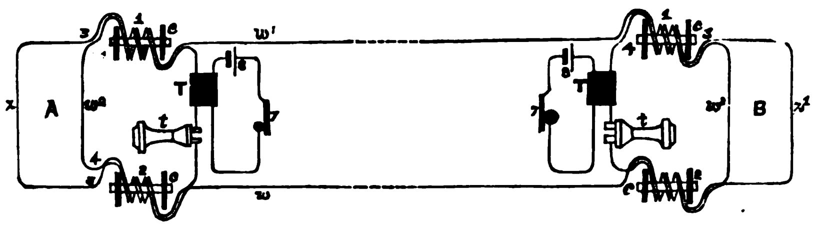


Fig. 1.

Fig. 2 shows a metallic circuit with its appliances similar in every respect to the circuit and arrangement described in Fig. 1, but with the addition of an earth branch extension-circuit at both terminal stations. This branch w' is at both ends united to the double wire circuit at a point z or z', equidistant from the two converting coils 1 and 2, and passes through the regular telephone instruments to earth at g. This earth-branch extension may of course be constructed of any convenient length extending to the stations G and H, which may be located at a considerable distance from the points z and z'.

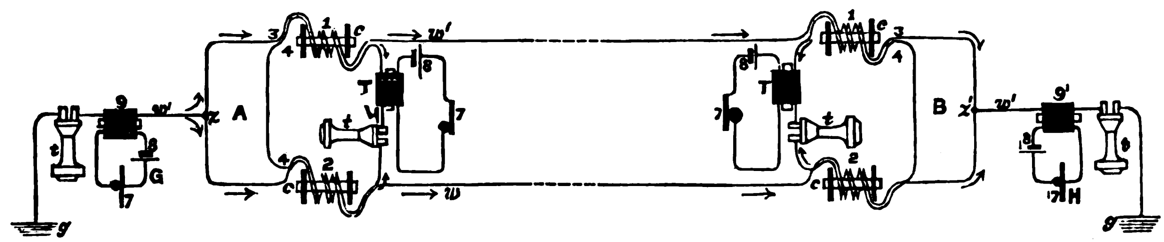

Fig. 2.

The telephone instruments shown at each of these stations G and H consist in this case of a receiving telephone t, and a transmitter 7, in a primary circuit including a battery 8, con-nected with the branch line w' through its induction coil 9.

The instruments in both terminal branches are alike, and a description of one will thus serve for both.

Mr. Barrett has found in practice that stations A and B may freely exchange oral communications without affecting the instruments at stations G and H, and that G and H may in like manner communicate without interfering in any way with messages which may simultaneously be in course of transmission between A and B.

The usual signalling appliances are of course in practice combined with the above system, as will be readily understood.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

The first meeting of the winter session of this society was held at the Institute of Civil Engineers last night, when Mr. Gisbert Kapp read a paper "On the Predetermination of the Characteristics of Dynamos," which we give *in extenso* below. Mr. Kapp, in his opening remarks, pointed out that Drs. J. and E. Hopkinson had practically covered the same field in their paper, which has just been published by the Royal Society, but his own paper had been written before their work became known. The discussion which followed the reading of the paper will be resumed at the next meeting of the society. In the meantime we shall give here some interesting and important facts which were communicated by Prof. Ayrton, reserving the remarks of the other speakers until the completion of the discussion.

Professor Ayrton congratulated Mr. Kapp upon having succeeded in developing a sound working theory of magnetism and magnetic induction, in place of the mathematical abstractions which hitherto went by that name. He particularly referred to the results obtained by Professor Rowland, which had not been confirmed by any experiments of his own, or, so far as he knew, of others. At the time when Mr. Kapp read his important paper on "Dynamo Electric Machinery," before the Institute of Civil Engineers, it happened that his colleague, Professor Perry, and himself were working on the same subject of magnetic resistance; and some months ago they had already prepared a paper upon the subject. At the period of Mr. Kapp's first paper they did not feel quite satisfied that the formula in which he expressed the magnetic flow by dividing the excitation by the sum of three magnetic resistances, belonging respectively to the iron in the field, the iron in the armature, and to the air gap, did accurately represent the true state of the case. What was termed leakage did undoubtedly exist for all degrees of magnetisation, even the lowest. It therefore seemed necessary to take into consideration the magnetic resistance of the whole of the air by which the magnet was surrounded, and not merely that between the poles and the armature. The question then arose in their minds whether the true expression for the resistance of a magnetic circuit containing an armature was not one in which the resistance of the iron and the air space was treated as one path, *combined in parallel with another path whose resistance was represented by that of the whole of the surrounding air.* In this way the case of any number of armatures whose resistances were separately known could be represented by formulæ precisely similar to those for parallel electric circuits, when the resistance of the surrounding air was included as one of the paths. Upon appealing to experiment these views received decided confirmation. Moreover, even for low degrees of magnetisation the resistance of the air was found not to be so large as had usually been assumed in comparison with that of the iron. For instance, in one case in which a horse-shoe electro-magnet had itself a resistance represented, in certain units, by the figures 0·5082, that of the air surrounding it was only 3·125; and that of an iron armature 5in. in length and separated from the poles by a 1-32nd gap was 3·697. Another peculiar result was that the magnetic resistance was apparently exactly the same, whether the armature was placed in a position corresponding to that usually assumed to be in the natural line of magnetic flow, or whether it was at right angles to that position.

[In Mr. Kapp's paper below we are unable to reproduce the figures, but our readers will not on that account find any difficulty in following the author.]

THE PRE-DETERMINATION OF THE CHARACTERISTICS OF DYNAMOS.*

By Gisbert Kapp, Associate.

If we know the number of magnetic lines of force which pass through the cross section of the armature core at the neutral points, the internal electromotive force developed can easily be calculated from the winding and the speed. Adopting, for convenience of calculation, as a unit line that which is equivalent to 6,000 lines in the C.G.S. system of measurement, we have

$$E_a = z_1 N t n 10^{-6},$$

where E_a is the E.M.F. developed, z_1 the number of unit lines passing through both neutral sections, $N t$ the number of conductors counted all round the armature, and n the speed in revolutions per minute. This formula applies equally to cylinder, disc, and drum armatures, but in the former two types $N t$ represents the number of complete convolutions on the armature, whilst in the latter it represents twice that number. The formula also applies equally to bipolar and multipolar machines, the only difference being that in the latter cases the neutral sections to be considered are not diametrically opposite.

The question to find the E.M.F. of a given armature therefore resolves itself into the determination of z_1, the number of lines passing through the armature core; and in the following I would submit a suggestion for the solution of this problem, if the constructive details of the machine, the exciting power, and the quality of iron are known. Stated in other words, the problem is to construct the characteristic curve of a dynamo from its drawing without having recourse to experiment.

Since the usual characteristic representing the relation between exciting current and electromotive force depends on the speed, it is more convenient to use the characteristics of magnetisation, where abscissæ represent exciting power and ordinates the number of useful lines. As far as I am aware, the only attempt to represent the relation between these quantities mathematically is the ingenious and very simple formula by Fröhlich, which has been further developed by Prof. Silvanus Thompson. According to the original notation of Fröhlich the effective magnetism (M) is represented by

$$M = \frac{i}{a + b\,i},$$

where i is the current of a series-wound dynamo (therefore proportional to the exciting power), and a and b are constants to be determined experimentally for each machine. For an infinite current the magnets become saturated, and the effective magnetism equals $\frac{1}{b}$. If now absolute saturation be considered as unity, and actual magnetisation be expressed in reference to it, the formula is further simplified to

$$M = \frac{i}{a + i}.$$

In this case the constants to be determined experimentally are a and the E.M.F. corresponding to saturation. In Prof. Thompson's well-known modification of this formula, $H = \frac{G \kappa S i}{1 + \sigma S i}$; there are also two constants which require experimental determination—G, the geometrical constant depending on the configuration of the machine, and the saturation coefficient σ "which is the reciprocal of that number of ampere turns that will bring the magnet up to such a degree of saturation that its susceptibility is halved."

Now this necessity of making at least two experiments in order to determine the value of the constants in each particular machine limits the use of either formula to such cases where the new machine differs from that experimented upon in the winding only, but not in size or type. There is another drawback. Fröhlich himself says that his formula only gives correct results if used between limits for which his "curve of current" can be considered as a straight line, and, generally speaking, it will therefore not be possible to construct the whole of the characteristic of magnetisation, even if we have made the necessary experiments for the determination of the constants.

It was with a view to do away with preliminary experiments of the nature alluded to that about two years ago I began to make use of a formula by which the strength of field could be determined from the electrical, magnetic, and mechanical data for each design of dynamo. This formula is based on the conception of magnetic resistance—a quantity proportional to the ratio of length divided by area, and in so far analogous to electrical resistance, but differing from the latter in this respect, that the co-efficient with which the ratio of length to area must be multiplied (the specific resistance) is not a constant, but varies with the density of lines flowing through the iron, and reaches infinity at absolute saturation. As regards air or non-magnetic metals this coefficient is, however, assumed to be a constant. The formula, as published by me in a paper read last year before the Institution of Civil Engineers, is

$$z_1 = \frac{P}{R_a + R_a + R_f},$$

where P is the exciting power in ampere turns applied to the horseshoe magnet which produces the lines z_1, and R_a, R_a, R_f, are the magnetic resistances of the air space, armature, and field-magnet respectively. The resistance of air space is found by multiplying twice the interpolar distance given in inches (twice because the lines must leap into *and* out of the armature) with the constant 1440, and dividing the product by the polar area. In this case the numeric 1440 is the specific magnetic resistance of air in the arbitrary system of measurement we have adopted. The other two resistances are for very low degrees of magnetisation, found in like manner by determining from the drawing of the dynamo the average distances through which the lines flow in armature and magnet, and dividing by the respective areas; the ratio in each case being multiplied by the numeric 2, which represents the initial specific magnetic resistance of annealed wrought iron. The above empirical formula is only correct for low degrees of magnetisation, and consequently for comparatively weak exciting powers. Assume we have made the calculation and determined the ratio (represented by a straight line) between E_a and P for a given speed. If we now work the dynamo under these conditions, we find that the actual E.M.F. observed is either equal to or slightly higher than the calculated E.M.F., but seldom lower. In other words, the actual initial value of the magnetic resistance is either equal to, or slightly less than, the calculated value. This is probably due to the neglecting of the influence of edges of pole-pieces, and to errors in estimating the lengths and areas of the flow of lines. Nature finds the easiest way for this flow, and since it is obviously impossible for us in our calculation to hit on a still more easy way, we are likely to obtain (when working with the greatest possible

Digitized by Google

care) a slightly higher resistance. The error is, however, generally very small, and is of no influence on that part of the curve which is of practical importance.

Before entering into the question of how this part of the curve can be obtained, it will perhaps be best to illustrate by analogy to the voltaic circuit the conception on which the formulæ to be given are based. Let, in Fig. 1, R_a represent a certain resistance (corresponding to the magnetic resistance of the armature core), connected by resistances $\frac{R_a}{2}$ representing the two air spaces) with the poles (p p) of a voltaic battery having a resistance R_f (corresponding to the field-magnet) and an internal electromotive force P (exciting power).

Imagine at the first the apparatus well insulated, then the current z_1 is given by the ratio of P and the sum ($R_a + R_a + R_f$).

If now the battery be submerged into a badly-conducting medium, currents will flow as shown by the dotted lines, and consequently through certain cells a current flows which is larger than the useful current in R_a. It is impossible to say exactly in what manner these currents of leakage are distributed, but it is evident that the most serious loss must occur between the poles where the difference of potential is a maximum, and that in a given medium and arrangement of battery the total loss through leakage can be considered as approximately proportional to the difference of potential between the poles. Let the latter have the value p_1, then the current lost, ζ, equals p_1/ρ, if by ρ we represent the average resistance of the surrounding medium for this particular configuration of battery. We can also, with fair approximation, put the current in the battery—

$$z_2 = z_1 + \zeta.$$

Now imagine that by some means we can give to the electromotive force (P) of the battery any value between zero and that value which will produce the maximum current (z_1) required. It will then be possible to determine what electromotive force is required for each value of z_1 between zero and maximum. To do this we proceed as follows:—We determine first the difference of potential at the poles—

$$p_1 = (R_a + R_a) z_1 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

then the loss by leakage—

$$\zeta = \frac{p_1}{\rho} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

then the total current—

$$z_2 = z_1 + \zeta \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

then the loss of electromotive force (p_2) occasioned by the internal resistance of the battery—

$$p_2 = R_f z_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and, finally, the total E.M.F.—

$$P = p_1 + p_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

The submerged battery is analogous to a horse-shoe magnet, since the latter is always surrounded by a medium which allows the passage of magnetic lines. To the electromotive force of the battery corresponds the total exciting power applied to the magnet; to the currents z_2, z_1, and ζ correspond numbers of lines respectively created within the magnet core, passing through the armature, and lost by leakage; the analogy of resistances has already been mentioned.

Since for small degrees of magnetisation the resistances of armature and magnet are not very different from their lowest initial values, which are very small in comparison with the resistance of leakage, it follows that for the early stages of magnetisation leakage has very little influence on the exciting power; in other words, that the creation of leakage or waste field does not materially increase the expenditure of energy required to produce the useful field. For a more intense magnetisation, such as found in the usual working conditions of dynamos, the case is, however, very different. In the first place, the resistance of the armature has now considerably increased, and with it has increased at a still faster ratio p_1, that portion of the exciting power (or magnetic pressure at the field-poles, if I may be allowed to use a somewhat unscientific term) which is necessary to force the lines through air space and armature. The immediate result is a large increase of the waste field, which has to be provided for by the magnet; augmenting, therefore, the density of lines in the case of the latter considerably beyond the value which would otherwise correspond to the useful field. Hence large increase of magnetic resistance, and consequently also of exciting power. This fact—that the number of lines created must be sensibly greater than the number utilised—explains at once the necessity of making the area of the magnet core considerably larger than that of the armature core. If, with a view to get an equal density of useful lines in armature and field, and thus save weight, the cross section of the magnet be reduced to that of the armature, it will be found absolutely impossible to saturate the latter, no matter how much exciting power we put on. A machine so constructed would therefore be a failure, not only on account of lower voltage, but also because it could not be compounded. Dynamo makers have long ago found out by practical experience that to produce machines of high voltage as compared to the length of wire on the armature, and machines that by reason of their rising characteristics can satisfactorily be compounded, it is necessary to work with a high magnetic density in the armature and a low density in the field. Roughly speaking, if we only take the useful lines into consideration, the ratio is from 1 to ·5, to 1 to ·6.

Before the formulæ (1 to 5) can be used for the actual determination of total exciting power as a function of the number of useful lines in any given dynamo, it is necessary to make an assumption regarding the rise of magnetic resistance with increasing density of lines. Whatever may be the mathematical connection between these two quantities, it must be of such a nature that for low densities the rise of resistance is insignificant; whilst for a certain and definite maximum density, the exact value of which depends on the nature of the iron, this rise is infinity. Amongst the formulæ which might be devised to fulfil these conditions two fairly simple expressions naturally suggest themselves—the one where the increase of resistance is made proportional to the reciprocal of the difference between saturation density and working density, and the other where it is made proportional to the tangent of an arc which represents the degree of saturation to such a measure that 90deg. corresponds to absolute saturation. The value of either of these two assumptions, or of any other which might be suggested, cannot be argued out on theoretical considerations, as we know as yet too little of the laws of electro-magnets. The only way is to apply either theory to machines actually tested, and then see which fits in best with practical results. In this way I have found the tangent formula to give better results than the other, and to fit actual experiments with sufficient accuracy for practical work. Without pretending to give a scientific reason why this formula should be better than any other, it might be pointed out as at least plausible that a tangent function might enter into the relation between exciting power and magnetisation. If we assume the act of magnetisation to consist in the bringing of molecular magnets into approximate parallelism with the lines of force passing through the metal, whilst the force resisting magnetisation—which might be a passive one of molecular friction or an active one of inter-molecular attraction or repulsion—tends to turn the molecular magnets away from that position, we can consider each molecular magnet as the needle of a tangent galvanometer having a field of its own and a zero position which may possibly be different from that of its neighbours. Whatever the configuration of these molecular magnets may be, it is at least conceivable that the average angle through which they have been rotated is equal to that of a molecule which started from a position at right angles to the direction of the magnetising force, and that therefore the tangent of this angle is a measure for the current, or, rather, for the exciting power surrounding the core. The weak point of this theory is that it does not show why the angle of rotation should be proportional to the number of lines created, and therefore I do not put it forward as a true, but simply as a possible, explanation.

Whether true or not, the fact of practical importance is that we can by the use of a tangent function determine the increase of magnetic resistance at various stages of saturation in such a way as to accord with experiment, and that therefore the same formulæ can be used for the construction of characteristics of new machines. The only data (besides those taken from the drawing) which we require to know are—

1st. Z_1, the maximum number of lines which can with an unlimited magnetising power be forced through the armature core.

2nd. Z_2, the maximum number of lines which can be similarly forced through the magnet core.

These are figures which depend on the dimensions of the cores and the quality of the iron, and if we could rely upon obtaining always the same iron, a few experiments made once for all would suffice for all future machines. Let the degree of saturation in armature and magnet be denoted respectively by σ_1 and σ_2, so that

$$\sigma_1 = \frac{z_1}{Z_1},$$

$$\sigma = \frac{z_2}{Z_2};$$

then the actual resistance in the armature core is obtained by multiplying the initial resistance by

$$\frac{\text{tang.} \left(\frac{\pi}{2}\sigma_1\right)}{\frac{\pi}{2}\sigma_1},$$

and similarly for the field-magnet.

From numerous experiments made with my own machines, and from data kindly supplied by some other dynamo makers, I am enabled to give the following average figures for the density of saturation to be taken as a basis when using my formulæ*:—

	Lines per square inch.
Armatures—charcoal iron wire well annealed	25
,, ,, ,, discs ,, ...	22
Field-magnets—hammered scrap ,, ...	18

The superiority of wire over discs is possibly due to better annealing, but probably to the fact that in wire cores the lines run mostly in the direction of the fibres, whilst in disc cores they run as often across the fibre as with it. The inferiority of field-magnet iron as compared to armature iron is probably due to the difficulty of thoroughly annealing large masses. I have no records of experiments made with machines having field-magnets composed of thin laminæ. Perhaps some of the members present can give their experience on this very important point. It will be noticed that the figures here given, although by no means the highest which can be obtained with exceptionally good iron, are considerably higher than the maximum induction obtained by the important experiments made independently by Rowland, Bosanquet and Hopkinson.

The only explanation which suggests itself to me is that the samples experimented on by those scientists were not so good as the usual commercial iron now obtainable for dynamos. Suppose, then, that we know the quality of our iron and its density of saturation. This gives us the values of Z_1 and Z_2. We now proceed as follows:—We assume a certain number

* These figures are not to be taken as generally applicable, but simply as *averages* of the usual qualities of iron now obtainable.

Digitized by Google

of useful lines (z_1), and calculate the corresponding density (σ_1) in the armature core. The corresponding value of the function tang. $\left(\frac{\pi}{2}\sigma_1\right) / \frac{\pi}{2}\sigma_1$ (taken from a table prepared beforehand) is then multiplied with the initial resistance of the armature core (R_a), and added to the air resistance. The sum is multiplied with z_1, and thus we obtain p_1, the quantity which above was called the magnetic pressure between the pole pieces. The leakage of lines takes place under this pressure, and to obtain the exact number of the waste lines we must know the resistance of the space surrounding the machine. This resistance cannot be calculated in the same manner as that of the air space—so much depends on the configuration of the magnets on neighbouring portions of the iron bed plate, bearings, &c.; but from the character of the resistance of a non-magnetic medium it is evident that for similar types of a dynamos the value of ρ is inversely proportional to the linear dimensions of the machine. Thus this resistance can be found by dividing a constant by the diameter of the armature. An experiment made once for all is sufficient determine this constant for all sizes of a given type. Knowing ρ, we find the waste field $\zeta = \frac{p_1}{\rho}$, and the total number of lines created $z_2 = z_1 + \zeta$. The ratio of z_2 to Z_2 gives us the density in the magnet σ_2, and by again referring to the table we find the corresponding value of the function tang. $\left(\frac{\pi}{2}\sigma_2\right) / \frac{\pi}{2}\sigma_2$, with which the initial magnet resistance must be multiplied in order to obtain the actual resistance at that particular density. The product of this actual resistance with z_2 gives the exciting power (p_2) necessary for the field-magnet alone, and the sum of p_1 and p_2 is the total exciting power (P) necessary to produce z_1 useful lines. In this way we proceed to calculate P for various values of z_1, and, plotting the results in a curve, we obtain the characteristic of magnetisation, by the aid of which all the working conditions of the dynamo can be found. When determining the E.M.F. of the armature whilst a current is passing through it, account must be taken of self-induction, which has the effect of apparently lowering the characteristic. As this action does, however, concern more particularly the armature, and not the field-magnet, it does not belong to the subject of the present paper. To show the degree of approximation in calculating the exciting power in the manner above described Figs. 2, 3, and 4 have been prepared. These diagrams contain the calculated curves for three different dynamos, whilst the points indicated by little circles are values obtained in actual test of these machines. The lower curve in Fig. 2 is the predetermined characteristic of one of my own dynamos. It shows the number of useful lines passing through the whole armature as a function of the exciting power. The upper curve shows the total number of lines created. The ordinates between the two curves represent, therefore, loss by leakage. In order to enable anybody to check the correctness of these and the other curves, the data on which they have been obtained are given in a table below. The experimental points shown by little circles have for this dynamo the following values :—

z_1 =	715	1330	1490	1705
P =	3800	8600	10800	18600

By the courtesy of Messrs. Patterson and Cooper, and Messrs. Crompton and Co., I have been able to test these formulæ on their machines, and the result is given in Figs. 3 and 4 respectively. The curves shown in full lines are predetermined characteristics, showing the number of useful lines flowing through one half of the armature. (These machines, "Phœnix" and "Crompton," are of the double magnet type.) The experimental points in Fig. 3, which were kindly supplied to me by Mr. Esson, have the following values :—

$\frac{z_1}{2}$ =	207·5	594	792	910	1030	1070	1130
P =	1604	3840	5660	6900	9620	11240	12100

For purposes of comparison, a curve obtained by Fröhlich's formula has been added. This dotted curve shows values of $\frac{z_1}{2}$ obtained by using the function $\frac{P}{\alpha + \beta P}$, where α and β are constants which can be determined if two points of the actual characteristic are known. By choosing these two points near to each other a fair degree of approximation between the actual characteristic and Fröhlich's curve can be obtained, but only on that portion of the curve which lies between the points. Beyond it, on either side, the divergence is considerable. If one of the points is at $P = \infty$ (which would give, according to Fröhlich's new notation, the value of β as the reciprocal of the maximum magnetisation), the curve ought to be available from the chosen finite point up to saturation. In the diagram the finite point has been chosen at A, where P = 5,500, or about half the maximum exciting power which would be commercially profitable with this machine, since a larger power than 11,000 ampere turns would not produce any material increase of E.M.F. From the tendency of the characteristic, saturation has been assumed at $\frac{z_1}{2} = 1{,}150$. This gives $\beta = \frac{1}{1150}$ and $\alpha = 2{\cdot}32$. The dotted curve is found by using these values, and shows a considerable deviation from the points determined by experiment. By choosing the finite point A higher up the actual characteristic, a somewhat better accord between the latter and Fröhlich's curve could be obtained, but at the same time the range over which that curve can be used would be shortened.

As regards the curve of the Crompton machine (Fig. 4), the experimental points were kindly supplied to me by Mr. Swinburne, and have the following values :—

$\frac{z_1}{2}$ =	27	112	151	161	197	223	221	240	246	258	258
P =	1400	3300 & 3800	5300	5700	7700	8820	9050	10420	11300	12900	14060

The curves were found by using the following data :—

Table of Constants for the Three Dynamos Investigated.

Fig.	Z_1	Z_2	R_a	R_a	R_f	ρ
2	2200	2200	3·7	0·40	1·18	30
3	1200	1940	4·7	0·57	0·925	13
4	300	460	2·8	1·00	2·77	47

LEGAL INTELLIGENCE.

The Direct Spanish Telegraph Company (Limited) *v.* Bannatyne.

This was an appeal from the action which was fully reported in last week's *Electrician*, and which was heard by Vice-Chancellor Bacon, upon a motion by Mr. Neil Bannatyne, at one time Chairman of the Direct Spanish Telegraph Company (Limited), and now a preference shareholder in the Company, on behalf of himself and other holders of preference shares, against the Company, Sir James Anderson (its present Chairman), and the other Directors of the Company, for an interim injunction to restrain the defendants from acting on certain special resolutions passed by the Company for the reduction of their capital, and from presenting a petition to confirm the reduction.

Vice-Chancellor Bacon, having fully heard the case, granted the injunction asked for, with the right of appeal on the part of the defendants to a higher Court. Accordingly the case came on for hearing again on Wednesday afternoon in the Appeal Court, before Lords Justices Cotton and Fry.

Mr. Rigby, Q.C., and Mr. W. P. Beale (instructed by Messrs. Blunt and Lawford) represented the Company; Mr. Burton Buckley appeared for Sir James Anderson and the other Directors; Mr. Marten, Q.C., and Mr. H. B. Howard (instructed by Messrs. Murray, Hutchins, and Stirling) conducted the case for Mr. Bannatyne.

Mr. Rigby, in opening the case for the Company, briefly reviewed the nature of the previous trial, and the lines upon which the plaintiff's case had been conducted. He said that the real question that their lordships had to decide was whether a company could reduce its capital in cases where there were preference shareholders—whether, in other words, a case having arisen for the application of the statutory powers for reducing the capital, that power could be exercised with preference shareholders. In the present instance the case arose by reason of the total abandonment and picking up of the cable which formed part of the principal assets, so that a large portion of the original capital was no longer represented by available assets, and their lordships would have to determine whether in reducing that capital the preference shareholders were not liable to have their capital reduced *pari passu* with the others, and whether or not there was anything in the bargain with the preference shareholders which amounted to that. He ought to say at once that it was hardly a question of competition between preference and ordinary shareholders, for the reports of the Company's meetings went to show that the majority of the preference shareholders were in favour of the reduction proposed. Of course if it were *ultra vires* to do so, any one shareholder, as Mr. Bannatyne, had a perfect right to object. The company was formed in 1872, for the purpose, among other things, of buying the submarine cable which then existed between the Lizard and some places in Spain, near Bilbao. The price paid for the cable was about £112,000, and for some time the Company went on raising that capital. Later on they issued, under powers to which he would call their lordships' attention presently, preference shares. The main object of that was for the purpose of purchasing the line in the Mediterranean, between Barcelona and some point in France, and for other purposes. The real question then was, what was the arrangement between the preference shareholders and the company, and was there anything in it which precluded the application to this Company of those provisions for reduction which the Legislature had made generally in regard to all companies? He would first ask their lordships' attention to the words of the Memorandum of Association, and they would see the position in which the capital stood. The material Articles were few in number. Article 7 of the Articles of Association authorised the Directors, "with the previous sanction of a special resolution of the Company, to increase its capital by the issue of new shares to such an aggregate amount, with such preferential right to dividend, and such priority in the distribution of assets, or subject to such postponement of dividends, or in the distribution of assets, as should in such special resolution be provided." He did not think he would trouble their lordships with Article 8, but Article 9 provided that "all capital raised by the creation of new shares shall be considered as part of the original capital, and shall be subject to the same provisions in all respects as if it had been part of the original capital, except so far as these Articles, or the resolution authorising the raising thereof, may otherwise direct." Article 10:—"The Company may also, by special resolution from time to time, reduce its capital, including any capital that may be created, and alter the amount and denomination of the shares." He did not know that any more of the Articles were of great importance to the case, but he would direct their lordships' attention to Clauses 103, 104, and 105, which read as follows:—(103) "The Directors may, with the sanction of a general meeting, declare a dividend to be paid to the members in proportion to their shares, and to the amounts paid up thereon respectively." (104) "No dividend shall

Digitized by Google

be payable except out of the profits arising from the business and property of the Company." (105) "The directors shall, out of the profits of the Company, provide a reserve fund to meet contingencies, or to form a sinking fund in aid of capital, or for equalising dividends, or for paying off by instalments or otherwise any subsisting mortgage or other debt, or for replacing, renewing, repairing, maintaining, or adding to the lines of telegraphic communication by land or sea, or the stations, apparatus, appliances, privileges, or other real or personal property connected with the business of the Company, or any part thereof, or for any other purpose connected with the business of the Company; and the Directors may invest the sum so set apart as a reserve fund, or any part thereof, upon such securities as they may select." The last provision was of vital importance to telegraph companies, seeing that they depended for their profits entirely upon the continuation in working order of their cables, and seeing that it was found by experience that cables did not last for ever, but might at any moment be stopped by being worn out, or become so much deteriorated as not to be worth repairing. They stood between two Acts. To reduce the capital in certain cases was permitted by the Act of 1867, and then the Act of 1877 added some legislation on the subject. The Articles he had read were the only ones referred to by the other side, and so far as he appreciated the case none of the others were of importance. He would now call their lordships' attention to the special resolution passed at an extraordinary general meeting of the shareholders, held on the 3rd of July, 1874, authorising the issue of the preference shares, such shares being "entitled to a fixed preferential dividend of 10 per cent. per annum," and further providing that if in any one year there was insufficient to pay the said dividend, it was to be made up out of the profits of succeeding years." Their lordships would see that the cumulative dividend, as it was called, was not confined to the profits of any one year, but the account could be carried on and the 10 per cent. would be added on, and the whole paid as soon as there was sufficient money to pay it with. What had taken place was this. It was known some time ago that the cable which they had originally purchased, and for which they had given £112,000, was in a very critical condition. It was not, however, known at the time whether it could possibly be repaired or not; but it was apparent that if the cable were lost they would be losing a valuable asset, and the question arose whether it was competent for them to go on paying dividends out of the current profits of the society from year to year without providing the means for making good that asset in case of accident. Counsel's opinion was taken, and it was pointed out to them that they must either lay by sufficient money to make up what was actually lost of capital to place themselves in a dividend-paying position, or they must reduce their capital by writing off, in fact, the asset that they lost, and that then they would be a dividend-paying Company. That was exactly what had happened by the loss of the cable. The matter was taken into consideration by the Directors, and after a great deal of consideration and vacillation they came to the conclusion that they ought to recommend the Company to reduce the capital, and he would call their lordships' attention to the resolution which was passed authorising the same. Mr. Bannatyne came to the meeting and argued the case on the one side, while the Directors put forth their views on the other, and then the voting was taken, which went in favour of the Directors' proposal. But undoubtedly Mr. Bannatyne was in the position, having voted against the resolution, to come to the Court and say, "You acted *ultra vires*." The resolution passed on the 30th of September, and confirmed on the 19th of October, 1886, was as follows:—"That in consequence of the abandonment of the Company's original cable, the capital of the Company be reduced from £190,000 (at present represented by 6,000 preference shares of £10 each, all issued and fully paid up, and 13,000 ordinary shares of £10 each, whereof 12.931 are issued and have £9 per share paid up, and 69 are unissued) to £95,000, and that such reduction be effected by writing off £5 per share from the amount credited as paid up on each issued share, and £5 per share from the nominal amount of each unissued share, the amount so written off the issued shares being capital not represented by available assets." There could be little doubt as to the fact—it had not been denied by his learned friend—that there was an amount of capital actually gone. It was not a question of speculation, because the Directors, after consulting with the shareholders, and with the consent of a general meeting, determined to pick up the cable and sell it as old material. They did pick up as much as they could, but it became a question with them whether they would get as much for selling it as would cover the expenses of picking it up. There was no doubt that the cable was no longer in existence. The whole question was whether the resolution was *ultra vires* or *intra vires*. They had had reports from electrical engineers, which had been laid before the Company, and which had been approved by the Company, and so far as the Company could settle the matter, they had settled it for themselves. Those reports distinctly said that the line could not be advantageously restored, and that an entirely new cable would have to be laid. By the Articles of Association the preference shares were part of the original capital of the Company in all respects—by virtue of the Clause 9—except in so far as the special resolution of the Company that created them made provision; and, being part of the original capital, the contention of the Company was that they were subject to Clause 10, which gave the Company power from time to time to reduce its capital. Was there anything in the special resolution to show that they were exempt by the terms of their bargain from Clauses 9 and 10 of the Articles? The only clause to be relied upon as amounting to an express variation was that in Clause 3 of the special resolution, which said that "the shares shall be entitled to a preferential dividend of 10 per cent. per annum, &c." It was quite true that in this particular instance it was provided that all the capital should be paid up on allotment; but he did not think that that was a clear construction of the clause, and for the purpose of construing it he would ask their lordships to say what it would have meant if the capital had been originally paid up by instalments. When they found that the scheme of the Company affected those shares as well as the others, except so far as it was altered by the resolution, gave dividends to the shareholders in proportion to the amount taken up, it would follow that if they had paid £1, £2, £3, £4, or £5, or any amount up to £10 on their shares, they would simply get 10 per cent. on the amount paid up. That was evidently the scheme of the Company. The provision in Clause 3 was not a provision that the preference shareholders should throughout all time receive £1 per share, which would be 10 per cent., and that they should have a preferential dividend of that amount, but that their dividend should be always a 10 per cent. dividend. That was the only bargain—that their dividend should always be a 10 per cent. dividend, and there was absolutely nothing to show that it was not so. The way in which the matter was argued in the lower Court was—"we (the preference shareholders) are entitled throughout all time to £6,000 a year as a first charge on the profits of the Company, and you are endeavouring to deprive us of that. In one sense that was true. If that sum were worked out it would be found that 10 per cent. dividend on £60,000 amounted to £6,000, but the true bargain confirmed in that clause was this:—"Your dividend shall always be a 10 per cent. dividend on your capital." But, on the other hand, the Company said that the capital was not a fixed but a varying quantity. They found that the Act of Parliament, passed in a perfectly general way, authorised all companies—given a certain state of things—that was to say, when there were no available assets to represent the amount to be reduced, as in this particular case—to write off that amount of capital. It was not stated with respect to one set of shareholders only. It was not said of companies in which all the shareholders were in the same position as regarded dividend. Nothing of the kind. That might be affected by a particular bargain in each particular case. If there had been an express bargain that there should be no reduction of capital, and they reduced the amount of dividend payable to the preference shareholders, that would have been a different thing, and if their lordships were to find anything in the contract to that effect, then he would bow to that decision. The whole of his argument, however, rested on this, that there was no such bargain, either expressed or implied, and that the actual terms of the contract, or the real meaning of it, amounted only to this: "Your dividends shall not be fluctuating; they shall not vary in amount; they shall not at one time be higher and at another lower. You shall always have on your capital for the time being, whatever that capital properly may be, a 10 per cent. dividend, and you shall have that as a first charge on the profits of the Company." Their lordships would again perceive that it was not by no means clear that the effect of the proposed resolution was against the interests of the preference shareholders. It was clear that if the Company had to make up a reserve fund, until they had supplied the capital that was lost it would take 10 years before the preference shareholders could get 1d. of dividend. After that time they might, but subject to the fact that the other cables—the other assets—were in such a condition as they might safely do so. He did not think it was for him or even for the Court to look too closely to the question of commercial advantage or disadvantage, but the Company gave a *quid pro quo* in the arrangement they wished to bring about. They paid 25 per cent. on the preference shares down on the nail in part payment of the arrears due to them, and the result would be that the preference shares would get, as things stood, a large amount of dividend in place of having the dividends postponed for a considerable number of years, and perhaps indefinitely; and besides they would get their 10 per cent. on the £5, which would represent their capital, instead of 10 per cent. on the £10. The real point, as it appeared to him, was—what was the bargain? If it was *ultra vires* to pass the resolution, it did not matter how many were in favour of it, any one could object to it. At the time when the Act was passed it was matter of common knowledge that it was the policy of the Legislature to allow reductions of capital. For his part he did not know how a reduction of capital could take place legally or effectually, except by reducing it equitably all round. He could imagine their adopting an alternative way as regarded a part of the capital, but practically they could not reduce it except it was all round. There was no doubt that the preference given by the clause was only as regarded dividend. The preference shareholders were to have a 10 per cent. cumulative dividend, but they had no preference as regarded capital. Supposing that the Company were wound up—supposing that their other cables were lost—the preference shareholders would at once come in and share *pari passu*, on the ground that they formed part of the original capital, in the distribution of the assets. And a total loss of capital was somewhat analogous, at any rate, to the case (which had arisen) provided for by Act of Parliament, which entitled a company to say, "We have lost part of our assets; *de facto* there is nothing to represent one-half of them, and therefore we avail ourselves of the powers of the Act to write off that part of the capital which is not represented by available assets." They were only recognising in a legitimate manner, and in the way in which they were meant to do it by Act of Parliament, that one-half of the capital had gone. *De facto* there was not £10 worth of property in existence to represent each of the orignal preference share, but only £5 worth. But, although that capital had partially disappeared, the Act of Parliament pointed out in what way, by special resolution, and so on, they could make that reduction in their capital which was required to make it square with the facts. They held that it was part of the bargain that the Company might reduce its capital. It must not for a moment be forgotten that at the time the capital was issued it was only the Act of 1867 that was in force, but that gave the Company power by every lawful means to reduce the

Digitized by Google

capital. Of course they could not reduce it except in accordance with the Act of Parliament and in pursuance of the policy of the Legislature. The Act of Parliament prescribed how and under what circumstances the power for reduction arose. The Company were not responsible for that. They did not create it themselves. They could only look to the Act and read there when the case arose, and there could be no doubt that the occasion had arisen in the present instance that the Act of Parliament had prescribed. They were, therefore, in the position of saying, "Now that the case authorising the reduction has arisen, shall we, or shall we not, take advantage of it?" As in the previous trial, he contended that the action, Blisset *v.* Daniel, heard before Vice-Chancellor Wood, and reported at page 493, Vol. X. of "Hare's Reports," had no bearing upon the present suit, adding that when a power was given for the benefit of the whole of a partnership, they could not exercise that power with the object of benefiting a part only. Nothing of the kind in the present case could arise. In the first instance, it was an Act of Parliament which laid down the nature of the conditions under which, and the manner in which, preference and ordinary shareholders should vote. The preference shareholders got their right to vote out of the very clause which made theirs part of the original capital. Everything was regularly fixed by Act of Parliament and by their Articles, and he submitted that the shareholders of the Company had been convened in a proper manner, and had determined to reduce its capital under circumstances when it was quite right that they should do so, unless it could be shown that they had bargained not to reduce it. So far from bargaining that they should not do so, he apprehended that it was part of the bargain that they might do it—having power, no doubt, to place the preference shareholders in a preferential position both as regarded dividend and capital, but giving that preference only as regarded the dividend to the extent that they should have 10 per cent., and leaving them to the operation of the old clause, that their capital "shall be considered as part of the original capital, and shall be subject to the same provisions in all respects as if it had been part of the original capital," and so on. This was no doubt a most important question for preference shareholders in all companies. So far as they knew, in species, the matter was new. Perhaps it was rather extraordinary that it should be so, but there had not been so many cases of reduction of capital as to make it likely to be a common case of law; but every one, he thought, would, by referring both to the Acts of 1867 and 1877, which expressed the matter in perfectly general terms, form the opinion that the action of the Company was perfectly right and justifiable. In the case of Hutton *v.* the Scarboro' Hotel Company it was laid down that if the original Articles of Association did not contain a power, then it could not be exercised—it could not be added by special resolution. All would depend upon the Articles. He went as far as to say that in this case the power that was reserved for an increase of capital was a power which could be increased again and again. It was not exhausted on the first occasion, and an increase of capital could be made from time to time. He thought that was the usual construction of these clauses.

The Court then rose, and the case was adjourned till next week.

INCANDESCENT LAMP MANUFACTURE.

It is well known that legal questions are being fought out with regard to incandescent lamp patents. It is as well known that several meetings have been held by those interested in the manufacture to obtain collective action against what they term monopoly. The following letter from our reporter shows why we have not reported the last meeting. A report of the meeting was forwarded to us, and excellent reasons assigned for the non-admission of reporters, but we cannot break through our rules. The meeting was either public or private; if the latter it cannot concern our readers, if the former we cannot give a report not taken by our own representative.—[Ed. *E.*]

"Sir: I attended the meeting yesterday at the Cannon-street Hotel, convened by Messrs. Woodhouse and Rawson. I was, however, informed that it was a private meeting, but that I could stay if I could guarantee that my report should be seen by them before it was published. Of course, I could give no such guarantee, and stated so. On that I was informed that they had their own shorthand writer present, and that a report of the meeting should be forwarded to you.

"November 9, 1886."

COMPANIES' REPORTS.

West India and Panama Telegraph Company.

Report of the Directors, to be presented at the nineteenth ordinary general meeting of members, to be held at Winchester House, Old Broad-street, E.C., on Wednesday, the 17th November, at 12 o'clock noon:—

The amount to credit of revenue is £45,434. 18s. 7d., and the expenses have been £26,686. 5s. 10d., leaving a balance of £18,748. 12s. 9d., which, with the balance of £4,369. 4s. 3d., brought from last account, makes a total of £23,117. 17s. Of this sum the Directors have placed £7,000 to reserve, leaving an available balance of £16,117. 17s., with which it is proposed to deal as follows:—

	£	s.	d.
Payment of 8s. per share on account of arrears of dividend on the First Preference Shares.........	13,825	4	0
Balance to current half-year's account	2,292	13	0
	£16,117	17	0

The traffic receipts show a decrease of £5,039. 11s. 9d. as compared with the corresponding period of 1885, attributable to the depressed condition of the West Indian trade. The Company's ss. "Grappler" has been engaged in repairing the duplicate Jamaica-Porto Rico section. Owing to the great depth for many miles on each side of the break, which is in 2,400 fathoms, the Board decided, in executing the repairs, to lay the new cable required in much shallower water. After laying in 120 knots of new cable, the "Grappler" was compelled to discontinue operations in order to proceed to the repair of the Jamaica-Colon section, one break in which has been already made good. She is now engaged upon another interruption midway between Jamaica and Colon. A contract has been entered into with W. T. Henley's Telegraph Works Company for the manufacture of 250 knots of deep sea cable to replenish the stock in the West Indies. For the purpose of taking out this cable the ss. "Grappler" will shortly return to London. The Government of British Guiana have not acceded to the Company's proposal for laying a new cable between Demerara and Trinidad. The Board are still in communication with the colony on the subject. The colonies of British Guiana, St. Kitts, Antigua, and Dominica have renewed their subsidies for a further term of one year. With reference to the proposal of Her Majesty's Government to lay a cable between Halifax, Bermuda, and Jamaica, the Directors have satisfaction in announcing that they have been informed by the Secretary of State for the Colonies that, for the present, it has been decided to call for tenders for a cable between Halifax and Bermuda only.

Business Notice.—Mr. J. Slater Lewis informs us that he has transferred his business of telegraph engineer to the Telegraph Manufacturing Company (Limited), of which he himself becomes the managing director. We understand that this company has built extensive works at Helsley, Cheshire, and supplies every description of telegraph apparatus, including instruments, line wires, covered wires, batteries and insulators.

NOTES.

TORTOSA, SPAIN.—A company is being formed at Tortosa to light the city by electricity, the motive power being derived from the River Ebro.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended the 12th inst. amounted to £4,140.

ELECTRIC RAILWAYS IN THE STATES.—The following new lines are announced:—At Denison, Texas; at Fairmount Park, Philadelphia; at Port Huron, Mich.

THE WEST INDIAN CABLES.—The cable between Dominica and Martinique is repaired, and telegraphic communication with all the West Indian Islands is therefore restored.

THE BRITISH MUSEUM.—On Tuesday evening, about 6:45 p.m., the electric lighting arrangements at the British Museum suddenly broke down, and the Reading Room had to be closed an hour before the usual time.

LITTLEHAMPTON ELECTRIC TRAMWAY.—This scheme is being actively pushed on, the parliamentary notices and advertisements being now published. Volk's patent central channel system of conducting the current will be used.

EASTERN EXTENSION CABLE COMPANY.—We understand that the "Recorder," belonging to the Eastern Extension Company, has arrived at Thursday Island, and is now engaged in making the cable connection between this island and Cape York.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended Nov. 12 were £3,433, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th inst. are £2,118, as compared with £1,830 in the corresponding period of 1885. The July receipts, estimated at £5,057, realised £5,154.

THE NEW YORK ELECTRIC CLUB.—We have received a copy of the bye-laws of the Electric Club of New York City, which has been formed "to promote social intercourse among those interested in electrical matters, and to provide them with the conveniences of a club house."

THE JUBILEE OF THE TELEGRAPH.—It may not be generally remembered that next year is not only the Royal jubilee, but is also the jubilee of the electric telegraph in England. The first practical electric telegraph was worked between Euston Station and Camden Town on July 25, 1837.

SOCIÉTÉ FRANÇAISE DE PHYSIQUE.—At the meeting of this society, to be held this (Friday) evening, a paper will be read by M. A. Leduc on "Variations of the Magnetic Field Produced by an Electro-magnet," and M. H. Fontaine will read a further paper on his recent experiments on the transmission of force.

NASAL "GALVANO-CAUTERY."—Makers of medical electric appliances will find an article which should interest them in last week's *Lancet*, where Dr. Havilland Hall describes several successful operations for the treatment of sneezing fits, hay-fever, asthma, &c., by electric cautery of the mucus membrane.

EXPORTS OF TELEGRAPH APPARATUS TO SPAIN.—From the *Board of Trade Journal* we learn that during the month of September the export of telegraph wire and apparatus to Spain, under the new commercial treaty with that country, amounted to over £14,000, against only £44 in the corresponding month last year.

THE DIRECT SPANISH TELEGRAPH COMPANY (LIMITED) *ats* BANNATYNE.—The appeal against the decision of Vice-Chancellor Bacon in this action, which was partly reported in *The Electrician* last week, is down for hearing to-day, and we shall be able to give the continuation of the report in next week's issue.

ELECTRICAL SMOKING CONCERT.—The Electrical Engineering Football Club, of 12, Prince's-street, Hanover-square, held their first smoking concert on Wednesday, 17th inst., at the Masons' Hall Tavern, Basinghall-street. Messrs. A. E. Braddell and G. S. Aspinal presided at the piano. The next concert will be held Dec. 7th.

A NEW EXPERIMENT.—We learn from *l'Electricien* that a M. H. Dunville pledges his scientific reputation to the accuracy of the following observation:—If two glasses of water be placed, one upon the north pole of a powerful magnet and the other upon the south pole, in four or five minutes the former acquires a slight alkaline reaction, while that on the south pole becomes slightly acid."

PROPOSED ELECTRIC TRAMWAY AT BRAY, CO. WICKLOW.—Notice is given of intention to apply to the Lord-Lieutenant for an order in Council to authorise the construction, maintenance, and working by electricity or horse-power of a tramway at Bray, Co. Wicklow, about one mile in length. Messrs. Hamilton and Craig, 30, South Frederick-street, Dublin, are the solicitors for the promoters.

THE SOCIETY OF TELEGRAPH-ENGINEERS.—The next meeting of this society will be held at the Institution of Civil Engineers, on Thursday, November 25th, 1886, at 8 p.m., when the discussion on Mr. Gisbert Kapp's paper on "The Predetermination of the Characteristics of Dynamos" will be resumed, and a paper on "Some Experiments on Secondary Cells" will be read by Mr. James Swinburne.

THE ELECTRIC LIGHT ON THE DARDANELLES.—A Central News telegram from Constantinople says:—"The electric light on the heights of Siddul Bahar, at the entrance of the Dardanelles, has been completed, and has given so much satisfaction to the military authorities that further apparatus of a similar kind has been ordered for the other fortresses which command the different bends of the channel up to Nagara."

EDINBURGH INTERNATIONAL EXHIBITION AWARDS.—We are pleased to note that at the above-named Exhibition a gold medal was awarded to Messrs. Laing, Wharton, and Down, as exhibitors of the Thomson-Houston arc lighting system. During several months past a Thomson-Houston incandescent machine has also been run successfully at the Edinburgh Exhibition, but it seems to have attracted very little attention.

PARIS INTERNATIONAL EXHIBITION, 1889.—The first meeting of the recently appointed committee on electro-technics in connection with this Exhibition was held on November 8th. M. Mascart was elected president, and four vice-presidents for the sub-sections were appointed as follows:—Lighting, M. Bartel; experimental work, M. Becquerel; dynamos and motors, M. Maurice Levy; telegraph, telephones, &c., M. Blavier.

THE PHILADELPHIA "CONDUIT" LINE.—The principal difficulty which has hitherto been experienced with the Philadelphia "Conduit" line has arisen from the immense numbers of

Digitized by Google

caterpillars which have persisted in making themselves as objectionable as possible, and multitudes have died happy in the consciousness that their mangled remains would reduce the insulation of the circuit. As yet, however, they have not succeeded in actually breaking down the line.

THE MANCHESTER JUBILEE EXHIBITION.—In Section III. of this Exhibition, which is devoted to electro-chemistry, it is intended to exhibit the historical and modern methods adopted in the several branches of the art of electro-metallurgy, such as gold, silver, platinum, nickel, and copper plating, the purification of metals by electrolysis, and generally to illustrate the connection between electricity and chemistry. Application for space should be made not later than the 1st of December.

MANUAL ENGINE FOR DRIVING SMALL DYNAMOS.—Mr. Sellars, of Birkenhead, has devised a manual engine, worked by self releasing grips, and a rope passing over pulleys, with a maximum of friction, by which one man can drive a dynamo with sufficient speed to maintain a couple of 10-candle incandescent lamps. The maker suggests that for the various purposes to which a current of short duration may be applied, this machine will often prove more convenient and economical than the use of batteries.

ELECTRIC LIGHTING OF TRAINS.—The following paragraph appeared in a recent issue of the *Globe*:—"The London, Brighton, and South Coast Railway Company have given an order to the Railway Electrical Contractors (Limited) for a considerable extension of the system of lighting railway carriages by electricity, which has been successfully in operation on the line for some years." The company referred to are the proprietors of the Stroudley-Houghton system for the electric lighting of trains.

THE BARTHOLDI STATUE.—Whatever the merits of the electric light installation by means of which Bartholdi's colossal statue of Liberty is represented as enlightening the World, just outside New York, the absurdity of the erection, as we suspected all along, has not escaped the notice of the American people. A Canadian contemporary, *The Week*, states that the nation that has received the gift treats it with extreme levity, the comic papers transforming the goddess into an indignant wife, with a candle held aloft, receiving her belated spouse.

A BIG FERRANTI.—A correspondent informs us that Messrs. Hick, Hargreaves and Co., of the Soho Ironworks, Bolton, have just built a large dynamo to the order of a London electrical firm. The machine is of the Ferranti type, and is intended for the supply of 5,000 lamps, apparently 16 candle-power each. The armature is 9ft. in diameter; the weight of the field-magnets and frame is about 20 tons. The same firm are supplying a Cortiss horizontal engine of 500 horse-power, from which it is intended to drive the dynamo by rope gearing.

THE DISTRIBUTION OF ELECTRICITY.—The following paragraph appears in several of the American journals:—"Mr. G. Westinghouse (the inventor of the Westinghouse air brake) has taken out a patent for a new method of distributing electricity for lighting and other purposes, which, it is said, will cheapen the cost of lighting very much, and enable the electric light to compete much more successfully with gas. It is said to effect a saving of 95 per cent. as compared with Edison's system. A test with a main circuit wire of less than a quarter of an inch in diameter carried the current for 850 sixteen candle-power lights a distance of three miles."

THE SILVERTOWN COMPANY.—The cable steamer, "International," arrived at the moorings off the Silvertown Works, on Wednesday, the 17th inst., on her return from repairing and in part renewing one of the Havanah Key West cables. On account of the depth of water, and the strong currents running along the North Coast of Cuba, considerable difficulty has been experienced in effecting this repair, which has been successfully completed by Theophilus Smith, Mr. March Webb being chief electrician. Mr. Smith has been greatly aided by the local knowledge of Mr. M. Hellings, the cable manager of the International Ocean Telegraph Company.

THE LIVERPOOL ELECTRIC SUPPLY COMPANY.—The *employés* of this firm had on Saturday an excursion to Chester, which included dinner and tea at the Queen's Head Hotel. The project originated with the men employed in connection with the lighting at the "Shipperies," which had been so successfully carried out by the company. A very pleasant day was spent, and the health of the managing directors, Messrs. Holmes and Vaudray, was drunk with enthusiasm. Under the superintendence of these two gentlemen the Liverpool Electric Supply Company has carried out a large amount of excellent work in Liverpool and the neighbourhood during the five years of its existence.

ECONOMY OF ELECTRIC LIGHTING IN MINES.—Speaking at the recent meeting of the Montana Company, Mr. John Bayliss said, referring to the introduction of the electric light, that the total cost of the installation had been $3,665, and that the cost per month for working, including maintenance and interest on the capital, was $250. The old system of lighting cost $500 a month, so there has been a saving on this item of $3,000 a year on an expenditure of $3,365. Beyond that there was the untold saving arising from the comparative immunity from fire by the electric light, compared with the position under the old system of oil and candles. It was intended to extend the installation to the new 60-stamp mill, but the cost would not exceed $1,200.

SPANISH TENDERS.—The Madrid *Gazette* announces that on the 4th of December next tenders will be received at the office of the Director-General of Posts and Telegraphs, and simultaneously at the telegraph offices of Victoria, Burgos, Palencia, and Soría, for the supply of 7,000 posts for the service of the State telegraphs, viz., 2,000 of a length of 6 metres, 4,000 of 7 metres, and 1,000 of 8 metres. The maximum prices fixed by the authorities are 8, 9, and 10 pesetas each respectively. Tenders are also invited on the 11th December, at the central offices of the Post and Telegraph Department, Madrid, and simultaneously at Lerida, Gerona, Barcelona, and Tarragona, for 2,900 telegraph posts, viz., 2,600 of 6 metres at a maximum price of 8 pesetas each, and 300 of 8 metres at a maximum price of 10 pesetas.

THE BRIGHTON ELECTRIC RAILWAY.—This line is now repaired. Owing to the withdrawal of the shingle on which the line was placed a viaduct about 480ft. long has been built to carry the line. The work occupied three weeks, during which time the cars ran only between the Chain Pier and Kemp Town. On Saturday last the Lord Mayor of London (Colonel Sir Reginald Hanson), Mr. G. H. Puleston, M.P. for Devonport, and a numerous party, visited the line and inspected the various arrangements for working it. The party also took a double journey on the cars, and seemed most pleased with the arrangements. A short time ago Lord Augustus Loftus, the late Governor-General of New South Wales, visited and inspected the undertaking with a view to its introduction into Australia.

"ENCORE CREIL."—If any of our readers still retain any interest in the discussion of the results of M. Deprez's experi-

Digitized by Google

ments at Creil, we commend them to the current number of the *Revue International de l'Electricité*, which contains an article entitled, "La Vérité sur les expériences de Creil Entraits du rapport de M. Maurice Lévy, *modifié* par E. Boislet," The *modifications* are effected by the insertion in the body of the original report of numerous words, sentences, and paragraphs which are distinguished by being printed in italics. The alterations are in general such as to flatly contradict the assertions of the original; they are inserted with considerab'e literary skill, and the result is a very lively paper of some eight or ten pages in length. However, we have already had our say in the matter, and do not see the necessity for pegging away at the subject in the way that the French press does.

Telegraph Clerks and the Civil Service Commission. On Saturday evening a large meeting of telegraph clerks was held in Edinburgh to consider what steps should be adopted to obtain the necessary information and evidence to appoint witnesses to attend the meetings of the Royal Commission of Inquiry. Much satisfaction was expressed that the department had been selected on its merits as one of those branches of the civil service which was entitled to be inquired into. The fact that it has been included along with other departments showed that it had at last been recognised as one of great importance, and there was no doubt that in the course of investigation facts would be elicited proving that the telegraph department was second to none of the minor branches. A resolution to this effect was passed, and a vote of thanks awarded to Mr. Puleston, M.P., who has been mainly instrumental in bringing this matter to its present issue.

Contich, Belgium.—A correspondent sends us the following interesting account of a forthcoming Belgian central lighting station. The municipality of Contich is about to grant a concession to the *Société d'exploitation de force motrice and d'éclairage* for a town installation. The streets will be lit with arc lamps, and up to the present time private installations to the extent of about 300 incandescents have been arranged. Two installations for the transmission of force have also been contracted for, one of 12 and the other of 300 horse-power. The financial arrangements are as follows:—Incandescent lamps, 4 centimes per lamp-hour from 8 to 10 candles, 7 centimes per lamp-hour from 16 to 20 candles, 12 centimes per lamp-hour from 40 to 50 candles. Arc lamps, 40 centimes per lamp from 500 to 1,500 candles, 50 to 55 centimes from 1,700 to 2,000 candles. The charges payable upon first installation are as follows:—20 francs per lamp for an installation of 1 to 5 lamps, 18 francs per lamp of 6 to 25 lamps, 16 francs per lamp of 26 to 50 lamps, 13 francs per lamp of 51 to 100 lamps.

Recent Work of the E.P.S. Company.—The Electric Power Storage Company have just completed a successful installation of private house lighting at Colonel Stebb's residence at Scarborough. The plant consists of a 7-unit Elwell-Parker dynamo, supplying current to 33 cells of the 31 L type, and driven by a 7 horse-power gas engine. The main distributing switch-board is fitted with Drake and Gorham's patent measuring instruments and ring contact switches, and the whole arrangement of the installation was rendered by these gentlemen—who designed the work throughout—so simple in its working that, although it has been left in charge of a local man with no previous knowledge of electricity, no trouble in its manipulation has occurred. An equally successful installation has just been completed by the same company at the offices of the North British and Mercantile Insurance Company, which are now lit throughout by means of 160 incandescent lamps, supplied from a 9 unit dynamo and 53 E.P.S. cells. The power is derived from a 9 horse-power Otto gas engine placed in the basement of the building.

"The Revolution in Electrics."—Under this title the *Liverpool Courier* has an article commencing as follows:—"Since the appearance in this paper of the article on the above subject—the first announcement to the world of this new system—Mr. Quarrie, of Ulverston, reports that he meets a sullen opposition from so-called 'practical electricians,' all of which may go to delay his plans, but which will also emphasise in the manner it deserves the contemptibleness of the little-minded beings who have so tried to keep back simple truth. Electricians may cough, or cavil, or snap, or sneeze at this just as it may suit their various constitutions, but that the thing is workable, cheap, simple, endurable, and an overwhelming improvement and saving, they cannot gainsay; and more, they will not have long to wait to see it at work, which after all is the best argument." As an exponent of the views of "practical electricians," we need hardly say that, after our comments of last week, we await the outcome of Mr. Quarrie's experiments in fear and trembling, lest we should have to eat our words and hide our diminished heads.

Overhead Wires.—The *Lancet* of November 13th contains the following paragraph:—"The 'Works and General Purposes Committee' of the Metropolitan Board of Works has been good enough to agree with a Select Committee of the House of Commons in the opinion that something should be done about the overhead wires of the telegraph and telephone systems. This is encouraging, and ought to prove consoling to the surviving victims of accidents, and the friends of sufferers generally, during the long period which is only too certain to elapse before any serious step is taken in the matter. From a practical political point of view, we must confess that this accord between two 'authorities' in condemning an easily remediable evil does not appear likely to expedite a much-needed reform. Being agreed on the subject, the authorities concerned will probably shelve the question at issue. It is, then, necessary that the agitation commenced in the interest of public safety should be promoted with increased vigour. Doubtless there will be plenty of illustrative narratives of fact available for the purpose of argument as soon as the winter snows make their appearance."

Launch of a Cable Ship.—On November 12th there was launched from the yard of Robert Thompson and Sons, Southwick, Sunderland, an iron screw steamer, designed for the laying down and picking up of submarine cables, built to the order of Messrs. Pirelli and Co., Milan, Italy. As the vessel left the ways she was gracefully christened the "Citta di Milani" by Mrs. Pirelli, wife of one of the owners. The dimensions of the vessel are as follow:—Length, as per Board of Trade, 240ft.. breadth 32·2ft., depth of hold 24ft., and she is fitted up with three tanks for holding cables, besides having the usual appliances of merchant ships. On the main deck there will be fitted a combined "picking up and paying out machine," by Messrs. Johnson and Phillips, London, driven by a pair of powerful independent engines; also on this deck are the saloon, cabins for officers, engineers, electricians, and cable hands. The saloon is neatly arranged, and fitted up in mahogany, rosewood, and maple, electro-plate fittings, electric light throughout, pneumatic bells, &c. At the bow and stern of the vessel are the sheaves and whiskers through which the cables are passed. The lifeboats are fitted with Sample and Ward's patent disengaging gear, and also patent sheaves for paying out and taking in cables. The engines for the vessel have been built by Mr. George Clark, Southwick, and are

Digitized by Google

200 nominal horse-power. The vessel being built on very fine lines, a high rate of speed is expected to be attained.

West African Cables.—The cable steamer "Silvertown" arrived in the Victoria Docks on Sunday, the 14th inst., after an absence of about four months and a half. During this period she has laid six cables on the West African Coast with landing places at Grand Bassam, Accra, Kotoonou or Porto Novo, at Principe Sao Thomé, Gaboon, and at St. Paul de Loanda. This vessel left London on the 3rd July, and returned, after steaming 12,000 miles and being absent four and a half months, without consuming the whole of the coal she took on board at Silvertown before starting on her voyage. The total length of cable laid by the "Silvertown" and her consort, the "Dacia," during this period amounts to some 2,200 nautical miles, and, considering the climate and the landing of twelve shore ends through a West African surf, the staff of the Silvertown Company are to be congratulated on the successful termination of a difficult job. The operations were under the control of Mr. Matthew Hamilton Gray, the director of the expedition, assisted by Mr. H. Benest, chief telegraph engineer, Mr. N. S. Thomson, commanding the "Silvertown," Mr. J. Rymer Jones, chief electrician, Mr. W. S. Seaton, assistant to director, Mr. W. A. Tindall, commanding the "Dacia," Mr. G. Stoddart, superintendent engineer, Mr. D. Wilson Barker, commanding the "Buccaneer," and a staff of about 300 officers and men. Mr. R. E. Peake, assisted by Mr. Bent, represented Messrs. Clark, Forde and Taylor, the engineers to the West African Telegraph Company during the operations.

Callender and Webber's Underground Cable Conduits.—We have recently had an opportunity of inspecting the system of underground cable conduits which has been devised by Messrs. Callender and Webber. A section of some hundred yards was laid down nearly twelve months ago at the Borough-road Works of the Anglo-American Brush Company, where we understand that it will shortly be open to the inspection of all who are interested. Some time ago the opinions of electricians were divided upon the question of metallic or non-metallic conduits; but of late the tendency has been to give a decided preference to the latter type, especially for cables conveying any large number of watts, whether as heavy current or as high electromotive force. An ideal underground system for the distribution of electricity must secure the adequate protection of the cables when laid, provide easy and rapid means of repair, and in the majority of cases foresee future extensions and furnish means for increasing the number of conductors without fresh excavations or reopening the roadways. It is claimed that Messrs. Callender and Webber's system fulfils each of these requirements in a very high degree. The material employed is a natural bitumen, a substance possessing very considerable mechanical strength, together with a remarkably low temperature coefficient and a high insulation. It is impervious to water, and is unaffected either by gases or acids found in the soil. It can easily be bent to any required shape. The conduits are constructed in lengths convenient for handling, and we are informed that the work of jointing is very easily carried out by the application of heat; a collar of the same material is afterwards passed over, making the joint as good as any other part. The conduits are supplied with any required number of channels; and iron boxes for drawing in the wires are placed at suitable intervals. We may add, in conclusion, that the price of the material is not high, and from the well-known durability of genuine bitumen the cost of maintenance ought to be very small indeed.

Duplex Telephony.—With reference to the article upon duplex telephony which appeared in our columns last week, Dr. A. M. Roseburgh, of Toronto, writes to the American journals as follows:—"As attention has recently been called to duplex telephony, I desire to place on record what I have accomplished in this direction. I commenced experimenting over two years ago on the wires of the Bell Telephone Company of Canada, between Toronto and Hamilton, a distance of forty miles, the wires being placed at my disposal for the purpose by Mr. C. F. Sise, the general manager. My object was to utilise the metallic circuit system, so that either two subscribers or a subscriber and a central office operator at each end of a metallic circuit might be able to communicate simultaneously without interference. Through these and other experiments I was enabled to develop a duplex telephone system. I saw that the only solution of that problem was to generate the electrical impulse in both wires simultaneously and in opposite direction. After much experimenting I found that this could be done in several ways, as for instance, first, by using a transmitter with a double-wound secondary coil—one coil for each branch of the metallic circuit; secondly, using a transmitter with two induction coils, the primaries being connected either in series or in multiple arc; and, thirdly, by using what I call a "duplex repeater"—that is, a repeater with two coils, one in each branch of the metallic circuit. In using the duplex repeater the repeating circuit may be cut, one end grounded at the central office and the other end taken to the switch-board for the use of subscribers. By this arrangement two subscribers at each end of the metallic circuit may use the metallic circuit simultaneously, one using the "duplex repeater" and the other the ground wire. In the one case the currents traverse the two branches of the metallic in opposite directions; in the other case, the currents pass the two wires in the same direction, simply using the two wires as a double conductor. It is not difficult to render the central office receivers neutral to the currents for the subscribers' transmitters. A simple method is to wind the electro-magnet double, and insert one coil in one branch and the other coil in the other branch of the metallic circuit. I thus found that by charging the two branches of the metallic circuit simultaneously, and by using differentially wound receivers in the metallic circuit, the ordinary transmitters and receivers could be used in the subscribers' lines. This scheme has the obvious advantages of (1) rendering duplex telephony practicable, (2) facilitating long distance telephony, (3) eliminating induction."

Electric Lighting and Fire Insurance in America. By a somewhat singular coincidence, the views and policy which we advocated in our leader of last week on the question of fire insurance received strong corroboration in the course of a debate which took place a few days previously at the New York Electric Club. On this occasion, Dr. G. H. Benjamin spoke as follows:—"In 1882 the Board of Fire Underwriters of the City of New York adopted a series of rules relative to the precautions to be observed in the introduction of the electric light into buildings, which were published at the time, and with which you are all doubtless familiar. However well these rules may have been suited to the date of their promulgation, I believe it will be generally admitted that they are unsuited and inadequate to the present needs. With all new industries, or the practice of new arts, it has been the rule to allow the utmost latitude, and to impose as few requirements as is possible compatible with public welfare; this with the idea of lending encouragement and facilitating the introduction of such new art or industry; but when after a time the

Digitized by Google

industry or art has become well understood and established on a firm commercial basis, further and supplemental restrictions are generally imposed with the intention of making the employment of such art or industry absolutely safe for all concerned, those engaged in the practice thereof as well as those using or being benefited thereby." Dr. Benjamin then referred at some length to what he termed the reckless practice of certain of the American companies, who employ high tension currents, without proper precautions for the safety of their line-men. Coming to the question of fire risks, he proceeded:—"So far as the risks from fire are concerned, it is not necessary to enumerate them. Unfortunately, sad experience has made them only too well understood. Careless, stupid, and one may say criminally loose methods of wiring have been the rule rather than the exception in this country—of course, with some notable exceptions—and all those who have carefully studied the subject and are conversant with the needs feel that the enforcement of proper and stringent rules will not only allay public fears and restore confidence, but likewise materially benefit the industry. I contend, gentlemen, that we should look upon this subject in a broad light and free from the narrow prejudice of business. We should recognise the necessity, and not attempt to evade the responsibility. To make an electric plant perfectly safe may necessitate slightly increased cost of construction, although personally I am inclined to doubt the fact. But even admitting such to be the case, the perfect immunity from danger, the decreased cost of insurance, and the general confidence engendered in the public mind will be a good interest upon such additional outlay."

The Effect of Stress and Strain on the Electrical Resistance of Hard Carbon.—On this subject Mr. Herbert Tomlinson communicates the following note to the November number of the *Phil. Mag.*:—"Prof. T. C. Mendenhall has published in the September number of *Silliman's American Journal* an account of some experiments on the effect of pressure on the electrical resistance of carbon. These experiments deal not only with such comparatively hard rods of carbon as are used in the arc lamp, but also with the compressed lampblack seen in Edison's discs. I will first refer to the experiments on the hard carbon. Prof. Mendenhall seems to think that these are in accordance with some experiments made by myself; but this I rather doubt, for the change of resistance produced by pressure on the carbon rod used by him would appear to be considerably greater than any which was obtained by myself on carbon rods of a similar kind. Had I not employed a very sensitive arrangement for testing small changes of electrical resistance, one which in fact enabled me not only to detect but to measure a change of resistance of about 1 in 100,000, I might have failed in detecting any change whatever. The result arrived at by myself was that a pressure of 1 grm. per square centim. would produce a percentage decrease of only ·00000064. So that, if we assume the decrease of resistance to be proportional to the pressure, there would be required a pressure of 22,215lb. on the square inch to produce a decrease of resistance of 1 per cent. There is reason to believe that the pressure which would suffice to crush carbon is somewhere about 5,000lb. per square inch. If this result be at all correct, it would follow that pressure on the point of crushing the carbon would diminish the electrical resistance by less than ½ per cent. Prof. Mendenhall does not give any data by which the amount of change of resistance observed by him can be calculated; but, if one may judge from the tenour of his remarks and his arrangement for experimenting, it would seem probable that the ratio of change of resistance to pressure was considerably greater in his experiments than in mine. Further, Prof. Mendenhall seems to credit me with doing what I have not done; for, after describing his own experiments on the effect of pressure exerted in the same direction as the current, he goes on to say, 'It was also found that compression at right angles to the direction of the current produced a similar effect, but less in magnitude. These facts had been already announced by Mr. Tomlinson.' I have made no experiments on the effect of compression at right angles to the direction of the current, but I think it probable that if I had I should have found increase of resistance, and not decrease, to follow on compression exerted in the above direction. On the whole, then, I am of opinion that my experiments are more in accordance with those of Professors Sylvanus Thompson, W. F. Barrett, and others, than with those of Prof. Mendenhall."

The Effect of Stress and Strain on the Electrical Resistance of Soft Carbon.—Mr. Tomlinson continues the above cited note as follows:—"As regards soft carbon, such as is used with Edison's discs, I cannot speak from experience. I was, however, much interested in reading the account given by Prof. Mendenhall of his investigations on the subject, and especially with that part of the account which relates to the influence of time on the change of resistance of the carbon disc when the pressure is varied; inasmuch as some of my own experiments have shown a similar influence of time on the electrical resistance of the viscous metals zinc and tin in the form of foil, when traction was applied in a direction transverse to that of the current. At the same time I would venture to suggest to Prof. Mendenhall that his ingenious experiments may not be quite conclusive as to a considerable change taking place in the specific resistance of the carbon. After showing that very considerable change does take place somewhere in the circuit of the mercury in contact with the carbon button and the button itself, he substitutes for the soft carbon a disc of hard carbon similar in dimensions, and finds that a pressure of only 7 centimetres of mercury lowers the resistance by nearly 3 per cent.; and he says, 'There can be little doubt that this small reduction is due almost entirely to better surface contact produced by pressure.' From the above it is evident that the surface contact between the mercury and hard carbon was by no means good; but, writes Prof. Mendenhall, 'The faces of a soft carbon disc are always smooth and polished; the surface of hard carbon, on the contrary, is generally more or less rough and irregular. It would appear, therefore, that if the reduction of the resistance of soft carbon by increase of pressure is due to better surface contact, this reduction of resistance should be much more marked with hard than with soft carbon.' The above assumption is a very dangerous one to make, for the surface of the soft carbon might not be in the same state of cleanliness as that of the hard carbon. But even suppose we allow that there was better contact with the mercury in the case of the soft carbon than in that of the hard carbon, it does not necessarily follow that the observed decrease of resistance consequent on increase of pressure occurred in the carbon of the button. The buttons are, I believe, formed by compressing lampblack mixed with gum-water. Must we not suppose, then, that the particles of lampblack are bound to each other by the gum, and separated from each other by the gum, to a greater or less extent? Would not the diminution of resistance experienced in the body of the button when pressure was applied be due to one or both of the two following causes:—(1) Diminution of the resistance of the thin coating of gum between the particles of carbon; (2) Better surface contact between one particle of carbon and another? The influence of time on the change of resistance might be quite accounted for by supposing cause (1) to be at work."

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 8.)

The attraction which a magnet exerts upon a piece of soft iron is explained in a manner similar to the attraction of an electrified body upon an unelectrified conductor. If a piece of iron be held near the north pole of a magnet it becomes magnetised by induction, a south pole being induced near to the magnet and an equal north pole at the remote end, but the south pole being nearer to the pole of the magnet than the north pole of the iron, the attraction will exceed the repulsion, and the iron will be drawn towards the pole of the magnet.

Def. A line of magnetic force is a line which at every point is in the direction of the resultant magnetic force at that point.

If a card be placed in a horizontal position above a magnetic pole, or a number of magnetic poles, and if iron filings be sprinkled on the card and the card gently tapped to enable the magnetic forces to overcome friction, the iron filings will arrange themselves in lines, which are at every point in the direction of the resultant magnetic force at that point. This is explained as follows:—

Suppose the horizontal lines in Fig. 5 to represent lines of magnetic force, and that the particles of iron are spherical.

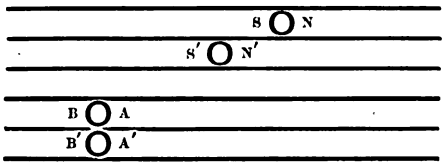

Fig. 5.

They will then become magnetised by induction in the direction of the lines of force. Now, consider the two particles S N, S′ N′. The attraction of the poles S and N′ will, notwithstanding the action of the other poles, cause the particles to move together, and link themselves to one another, forming the commencement of a thread in the direction of the lines of force. On the other hand, the particles A B, A′ B′, which are exactly side by side, will repel one another, so that there will be a tendency for the particles to form threads along the lines of force, and for these threads to repel one another so as to leave clear spaces of considerable extent between them. If the particles are not spherical, but elongated, there will be a tendency for them to become magnetised in the direction of their greatest elongation; but the particles will tend to set with their greatest lengths along the lines of force, and they will then act on one another like the spherical particles, but more strongly.

It will frequently be noticed that the region of the card just above the magnetic poles becomes completely bare of filings. This is due to the magnetic force being perpendicular, or nearly perpendicular, to the card. The filings then become magnetised vertically, and neighbouring filings repel one another until they have driven each other away from the poles. If the card is thin and the magnet very strong a great mass of filings may be held over the pole, the filings being built up into vertical threads.

If a cylindrical bar magnet be placed with one pole touching the card upon which the filings are sprinkled, and the axis of the magnet at right angles to the card, the filings will exhibit the lines of force due to a single pole, and will radiate uniformly in straight lines from the pole.

If two dissimilar magnetic poles be placed upon the card, the lines radiating from one pole will have a tendency to turn round and converge towards the other pole; and if the poles are of equal strength, and there are no other magnets in the neighbourhood, almost all the lines of force from one pole will sooner or later reach the other. (Figs. 1 and 2)

If two equal and similar poles are placed near together, the lines of force from each will, apparently, repel those from the other; and if a line be drawn, bisecting at right angles the line joining the two equal poles, all the lines of force will be turned aside so that none of them will cross this line. (Fig. 3.)

If a piece of iron (nickel, cobalt, or any other substance whose magnetic permeability is greater than that of air) be introduced into a magnetic field, the lines of force will be drawn aside so that as many as possible may pass through the piece of iron. (Fig. 4.) If a piece of iron be placed very near to one end of a bar magnet, most of the lines of force from that pole will pass straight from the end of the bar to the piece of iron. If the iron be removed, more of the lines of force will pass radially from the sides of the bar. This alteration in the magnetic field takes place in a telephone as the iron disc vibrates.

In dynamos and magneto-electric machines iron cores are frequently employed in order to draw the magnetic lines of force through the coils of the armature, instead of allowing them to be more uniformly distributed through the surrounding space. When the "keeper" is placed upon a magnet nearly all the lines of force of the magnet pass from the north pole to the south pole through the keeper, and very few pass through the surrounding air. Hence a magnet with its keeper attached has very little action upon any other magnets or magnetic bodies in its neighbourhood.

From the law of magnetic action stated above it follows that the force between two magnetic poles will be represented by the product of the strength of the poles divided by the square of the distance between them if the unit magnetic pole be properly selected.

Def. The unit magnetic pole is that north magnetic pole which acting *through air* upon an equal magnetic pole at a distance of one centimetre repels it with force of one dyne.

This is analogous to the definition of the unit of electricity, and the words *through air* are introduced for the same reason as in that definition. If a piece of brass, copper, wood, &c., be introduced between the magnetic poles the repulsion (or attraction) will not be sensibly affected, for the magnetic inductive capacity (analogous to specific inductive capacity in electricity), or, as it is more generally called, the magnetic permeability, of these bodies is sensibly the same as that of air. If, however, a piece of iron, nickel, or cobalt be introduced between the magnetic poles the effect will be very different, the magnetic permeability of these substances being much greater that that of air. If a magnet be completely surrounded by a soft iron case it will be protected from the influence of all magnets outside the case. These phenomena are best explained by help of the conception of magnetic lines of force. For example, when a body is surrounded by a soft iron case any lines of force tending to pass from one side of the case to the other will pass through the substance of the iron without reaching the enclosed body, which will thus be effectually protected from the action of the force. Iron watch cases prevent the hair springs being magnetised by dynamos, and iron cases to galvanometers cut off the action of the earth and of external magnets from the instrument.

The law of magnetic action above stated may be verified by means of Coulomb's torsion balance. For this purpose a bar magnet is suspended from the torsion head and a second magnet is introduced into the case so as to repel one pole of the suspended bar. The torsion head is turned until the suspended magnet rests in a definite position, and the distance between the repelling poles is measured and the torsion of the wire observed. On repeating the experiment with different distances between the repelling poles, and different amounts of torsion in the wire, it will be found that the repulsion between the poles, measured by the torsion of the wire (with the necessary corrections introduced) is inversely proportional to the square of the distance between the poles.

A second method consists in causing a small magnetic needle to vibrate at different distances from one pole of a very long vertical magnet. The square of the number of vibrations executed in a minute is, in this case, proportional to the force acting on one pole of the magnet. In this experiment allowance must be made for the action of the earth by swinging the little needle under the action of the earth alone, then introducing the long magnet, placing its pole at different distances from the needle, but in such a position that the force exerted on each pole of the needle by the large magnet is in the same straight line as that exerted by the earth

Digitized by Google

Def. The moment of a magnet is the product of the strength of either pole and the distance between the two poles.

The effect of a magnet upon other magnets or magnetic bodies at a considerable distance depends upon the moment of the magnet. If a bar magnet be bent into the form of a horseshoe its magnetic moment will diminish as its poles are made to approach each other, and if the bending be continued until the poles are in contact and a complete ring is formed, the magnetic moment will be reduced to zero, and the magnetised ring will exert no action at any point outside its own substance.

Def. The magnetic potential at a point is the number of units of work which must be done on a unit (north) magnetic pole to bring it from an infinite distance to the point.

Def. The magnetic moment of a magnet divided by its volume is called the *intensity* of magnetisation of the magnet.

If the intensity is not the same throughout we must take the magnetic moment of a small portion of the magnet, and divide by the volume of that portion, in order to obtain the intensity of magnetisation of the portion considered. If a uniform bar be not uniformly magnetised it will exhibit polarity wherever there is a change in the intensity of its magnetisation. If the intensity diminish continuously from the centre towards each end, there will be a north pole spread over the whole of the surface of one half of the magnet, and a south pole occupying the surface of the other half. If the intensity of magnetisation of a uniform bar were uniform throughout its whole substance, the poles would appear only at the ends of the bar. As stated above, it is impossible to realise this condition in actual magnets, and consequently the poles, instead of being concentrated at the ends, are spread over a considerable portion of the magnet in the neighbourhood of its ends. (See Fig. 1.) If a uniform bar were uniformly magnetised, the intensity of magnetisation would be numerically equal to the strength of the pole formed by a unit of area of the plane end of the magnet.

Though a bar is so magnetised that it has no true poles, its north and south polarity being each distributed over a considerable area of its surface, it nevertheless possesses a definite magnetic moment. For such a bar may be supposed to be cut into very fine threads, each of which will possess equal amounts of north and south magnetism at its ends, and these being practically points its magnetic moment will be the product of the strength of one pole into the distance between the two. The sum of the magnetic moments of all the threads will be that of the bar. It should be noticed that the threads will generally be curved and thinner near the ends if the bar be straight and of uniform section. But the simplest method of defining the magnetic moment of such a magnet as we are considering, whose poles cannot be defined, is to say that its magnetic moment is numerically equal to the couple which would be exerted upon it if placed in a uniform magnetic field of unit strength, with its magnetic axis at right angles to the direction of the magnetic force—that is, when placed at right angles to the direction which it assumes when perfectly free to move.

The behaviour of magnets upon one another, and upon magnetic substances like soft iron, is consistent with the hypothesis that magnetic action consists of a stress in a medium filling space; that there is a tension along the lines of magnetic force, and an equal pressure at right angles to them. The tension along the lines joining opposite poles explains the attraction which they appear to exert upon one another. The pressure in every direction at right angles to these lines explains the apparent repulsion between similar poles, the lines of force from which are diverted, and proceed side by side so as to exert, as it were, a pressure upon one another. If a piece of soft iron be placed near to a pole of a magnet, the lines of force from the pole will converge upon the iron, and thus between the pole and the iron the lines of force will diverge less than before, while as soon as they have passed through the iron they will diverge more than before. The tension along the lines will therefore act upon the iron in much the same way as a number of stretched elastic strings would act upon a smooth ring if the strings were radiating from a point and attached to the walls of the room, and the ring were placed upon them so as to draw several of them together. Such a ring would be pushed towards the point from which the strings diverged, and in a piece of iron in a magnetic field of variable intensity will be pushed towards the point from which the lines of force diverge—that is, towards the strongest part of the field, or to the pole of the magnet from which the lines of force originate. (See Fig. 4.)

Previous to 1845 it had been observed that bismuth and antimony if placed near the pole of a powerful magnet were repelled. In that year Faraday took up the subject and found that all the bodies upon which he experimented were affected more or less by the pole of a magnet, and that while many bodies, like iron, were attracted by a magnet or tended to move to the strongest part of the magnetic field, by far the greater number of bodies were repelled by a magnet or tended to move towards the weakest part of the magnetic field. Bodies which are acted upon in the same way as iron are called *magnetic* or, sometimes, *paramagnetic* substances. Those which behave like bismuth and antimony are called *diamagnetic.*

(To be continued.)

TESTING DYNAMO MACHINES.

BY JAS. SWINBURNE.

(Continued from page 10.)

THE TESTS.

As the first example of efficiency tests, that of two similar series wound machines may be taken. We will suppose them arc light machines of high electromotive force. The motor and generator have their pulleys connected by a belt, and the machines are coupled up electrically in series with a small machine, D. If the small machine is run, it will send a current

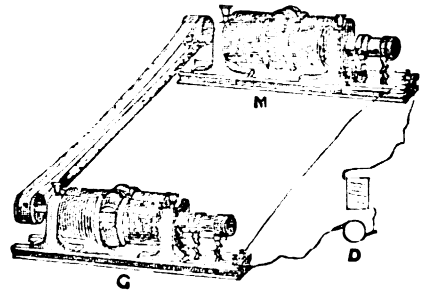

FIG. 1.

through the other two; but they will not start, as the torque will be the same in the two similar machines. This difficulty may be got over in several ways. Thus, the motor may have a smaller pulley than the dynamo. The size of the pulleys should be arranged so that the small one is to the large as the expected efficiency of conversion of the two machines is to 100—that is to say, the difference should be enough to allow for the loss of power due to Foucault currents in the armature, to magnetism, and to mechanical friction and belt slip. If the pulleys are not the right sizes, either the current will come wrong or the machines will not run at their normal speed. Let us suppose that the pulleys are chosen correctly, and that one of the machines, say the generator G, is to be tested. We will take its working conditions to be 2,000 volts, and 10 amperes at 900 revs. The small dynamo D is run up till it gives 10 amperes. The large machines will run quicker and quicker till the product of their torques and speeds is equal, or only differs enough to allow for belt slip; this will be at their normal speed if the pulleys have been correctly chosen.

We will assume hypothetical readings and work them out; G gives 2,000 terminal volts, the loss in the armature calculated from the hot resistance is 120 volts with 10 amperes, and in the field 120 volts. We will suppose the current to be quite steady; then, using Prof. Thompson's lettering for the sake of uniformity, the terminal electromotive force $e = 2{,}000$, on the brushes it is $\epsilon = 2{,}120$, and $\mathfrak{E}$ the armature

Digitized by Google

electromotive force is 2,240 volts. The motor M is $e=2{,}721$ and $\epsilon=2{,}601$, $E=2{,}481$. We have therefore $2{,}481-2{,}240=241$ volts spent in other ways than in overcoming the resistance of the wire of the machine, and the problem is to divide this loss fairly between the two machines. The losses in power, due to different causes, vary differently with the speed. For instance, the power lost by Foucault currents varies nearly as the square of the speed, while the loss from persistent magnetism is probably as the speed. It is most likely the best way to distribute the loss as the square of the speeds. In choosing the hypothetical readings the efficiency of conversion was taken at 95 per cent., so that G ran at 900 and M at 1,000 if there was no belt slip. Then the 241 volts, or 2,410 watts, will be distributed, M 1,330 and G 1,072. The armature of G gives 22,400 watts, so that the whole power given to G is 23,472 watts. In the same way the motor has $e=2{,}721$, $\epsilon=2{,}601$, $\mathfrak{E}=2{,}481$, so, as 130 watts are lost it transmits 23,480 watts. The eight extra is here due to the use of the slide rule. This supposes that there is no belt slip, but take the belt slip = 1 per cent. as the reading obtained by comparing the observed and calculated speeds of the dynamo shafts. A belt slip of 1 per cent. is 235 watts, and this power is part of the 2,410 watts not accounted for by the electrical resistance of the machine. This leaves 2,175 watts to be divided between the two machines. That gives M 1,211 watts and G 962 watts. The reason why the motor and generator were taken as similar machines in the example is that it is the only way this particular loss can be accurately determined. If the machines were not alike, it would be easy enough to determine the efficiency of the two machines taken together, but the loss in one alone could not be so well separated. We have found that the generator G receives 23,362 watts, which is spent as follows:—

	Watts.
Loss in armature by resistance	1,200
„ „ in field-magnets	1,200
„ „ mechanical friction, Foucault currents, persistent magnetism, &c., in the armature ...	962
Total loss in the machine	3,362

Efficiency, 84·6 per cent.

If the current is not steady, some precaution becomes necessary. The main current must not be measured with an ordinary ammeter, but an electro-dynamometer must be used. Such an instrument does not really indicate the current, but gives what may be called the virtual current, which, when multiplied by the virtual electromotive force, taken with an electro dynamometer voltmeter, without self-induction, gives real power spent in any part of the circuit that is resistance only—that is, has no electromotive force, induced or otherwise produced. Again, if the current is variable, the loss in the fields is greater. To get the loss in the fields, an electro-dynamometer, without self-induction, must be set to measure the power. It will not do to measure even the virtual volts and amperes with two separate instruments and multiply them together, for there is an electromotive force induced in the field coils when the current varies. This method cannot be applied to the armature, so the additional loss due to the variation of currents must be put in with the power unaccounted for by the resistance of the machine. It is probable that two machines, each of which alone gives a varying current, would, when coupled together and run at slightly different speeds, give an approximately uniform current. Instead of electrodynamometers, electrometers may be used. Enough has now been said to show the great advantages of this method of testing machines. The whole of the tests are taken without any mechanical dynamometers, and even the instruments need not be correct. It is a common practice among electrical engineers to measure resistances in B. A. ohms, and E.M.F. in what would be "legal" volts if they were a good enough shot to be anything at all; but all that is demanded with this method is that the instruments are correct throughout their scales with regard to themselves. If the instruments are not correct, or even consistent with one another, but consistent each with its own scale, the result is not a false estimate of the efficiency of the machine, but merely some slight errors in the distribution of the loss of power. The machine will also be run at a slightly different load.

If very great accuracy is not required the machines need not be similar, for if they are both arc machines, or at least both work with the same currents, the motor M may be any machine that is powerful enough. Care must then be taken to assess the loss of power and of belt slip properly.

If the machines are at the same speed the belt slip may be avoided by coupling the shafts of the machines together rigidly, as in Dr. Hopkinson's method. This lessens the friction of the bearings if the shafts are set exactly true, but the belt has the advantage that the machines are run more nearly under their normal conditions, and the tests are therefore more valuable, though the efficiency does not come out quite so high.

The arrangement in which the speeds of the dynamos with their normal currents depend solely on the relative diameter of the pulleys is defective, as it does not admit of any fine adjustment. This adjustment is managed by shunting one of the fields or one of the armatures. Thus, suppose G is found to run too fast, a shunt across either the brushes or the field of M will make it run slower.

If a low resistance voltmeter is used, with enough resistance in series to take the high electromotive force, it may itself take a current large enough to interfere with the test. An electrometer has not this disadvantage.

As our next example we will take two similar shunt or compound machines. First let them be shunt machines. We may suppose the test made with two Edison-Hopkinson machines like those tested at Manchester, particulars of which are given in *The Electrician* for 5th March, 1886. Fig. 2 shows two such

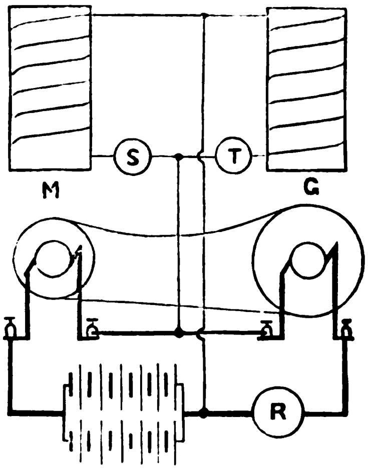

Fig. 2.

machines coupled with pulleys of different diameters. The first thing to do is to find the revolutions and relative sizes of the pulleys needed. The normal speed is 750, and the armature electromotive force $\mathfrak{E}$ is 108·6 volts, and ϵ and e are 105 volts. The machine is run as a motor with no load till it has a back electromotive force of 108·6 and a speed of 750. The field will then have a little less than 105 volts on it.

But the armature will be under conditions almost the same as when running at full load as far as Foucault currents, persistent magnetism, &c., are concerned. The electrical power now spent in the armature will give the data required for calculating the pulleys. Let the figures be 109 volts and 24 amperes in the armature, or 2,682 watts. The armature of the generator has a normal current of 364 amperes and an electromotive force of 108·6 volts. It will therefore want 39,600 + 2,682 to drive it; allowing 1 per cent. belt slip the motor must give 42,605 watts. As the motor will be going about 20 per cent. faster than the dynamo, 3,580 watts may be allowed for stray power, so the armature must get 46,185 watts. As the generator excites both machines the motor current is 352, and the back $\mathfrak{E}$ must be 131 volts; so the pulleys must be as 108·6 : 131. This assumes that the difference of current in the two machines makes no practical difference in the arma-

Digitized by Google

ture volts. The electromotive force at the brushes of the motor is $\epsilon = 134{\cdot}5$, so secondary cells or another machine must be inserted to add 26 or 27 volts to give 134·5 volts on the motor. These cells then supply the loss in the whole system. The machines are coupled up as shown in Fig. 2. The cells are shown in the main circuit, and there is an adjustable resistance R in the main circuit; the shunt circuits have also an adjustable resistance in each. To start the whole system the main circuit is made; the connections must be made so that the fields are to some extent excited by the cells to start with—that is to say, the resistance R must be in the armature circuit, but not in the field circuit. One objection to this method of testing two shunt machines may be the difficulty of starting. To start, the resistance S in the motor field circuit may be taken out, and the field of the generator left open and then closed through a high resistance which is gradually taken out. Let us suppose the machine started, and the main resistance and the shunt resistance adjusted till the generator is running under its normal condition. The power lost in each field is then determined, and the loss by armature resistance is calculated for each machine; the loss not thus accounted for is the total loss through friction belt, &c., and is distributed in the same way as in the case of the series machines. If the first calculation of the sizes of the pulleys is wrong, the motor must have its field altered by the resistance S, but it is not likely the error will be large enough to allow any perceptible error in the distribution of the stray power.

(*To be continued.*)

NOTE ON LIGHTING LAMPS BY PRIMARY CELLS, OR BY A COMBINATION OF PRIMARY AND SECONDARY CELLS.

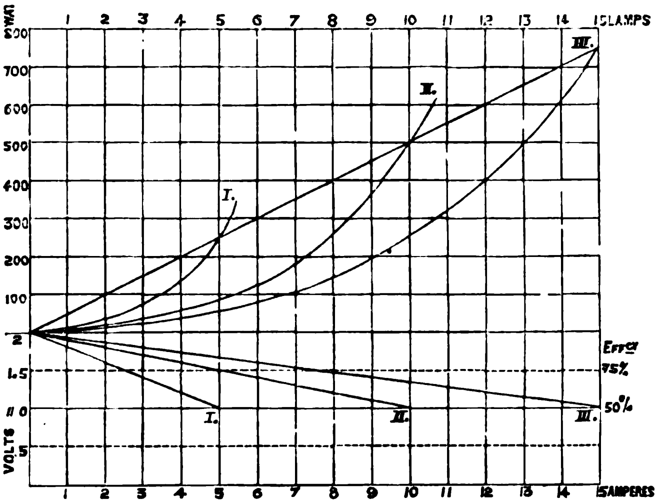
BY V. S. ALLPRESS.

Attention has often been called of late to the question of lighting by means of primary batteries, used either alone or in combination with secondary batteries, but little has been said of the relative efficiency of the two arrangements, and I have therefore worked out a few cases in order to show what the result might be in small domestic installations.

In Dr. Oliver Lodge's report on the Upward battery, the combined system of working is very favourably alluded to, and there is no doubt, if convenience alone is considered, such an arrangement has many advantages.

It will be seen, however, from the tables and diagrams that the cost of working is generally high, and that the output is somewhat restricted where lighting is to be done from a secondary battery, which is charged steadily for 24 hours, and discharged for a large portion of the same time; and it would appear, therefore, that if a simple automatic gear could be devised for switching in extra primary cells as the number of lamps in circuit increased, the difficulties of self-regulation, due to the high internal resistance of the batteries, would probably be overcome more cheaply than by the addition of a secondary battery.

In the examples I have taken it is assumed that 50-volt lamps requiring one ampere each are to be used, that the E.M.F. of each primary cell is two volts on open circuit, and that the internal resistance is one-fifth of an ohm per cell. It is also assumed that the efficiency of the system described by Dr. Lodge, in which one secondary and two primary cells are said to be needed for every couple of volts demanded in the circuit, is 50 per cent., although it is probably less than this; for, if 50 primary cells with the E.M.F. and resistance given



above are coupled up to 25 secondary cells, the charging current would vary from about five amperes when the back E.M.F. is only 50 volts to about three amperes when the E.M.F. of the charging current is allowed to rise to, say, 40 per cent. above the normal, during the latter part of the charging. It may be seen from the accompanying tables that the efficiency of primary cells would be 50 per cent. and 70 per cent. respectively when charging at these rates, and as the average efficiency of a secondary battery is not likely to exceed 70 per cent., the efficiency of the combination would be below 50 per cent. in any case, whereas that of a primary battery lighting lamps direct would in many small installations be much higher when the primary cells are arranged in two or three groups; and even with a single group, there is a distinct advantage on the side of a primary battery, if only a small number of lamps is required for many hours at a time.

I have tabulated the figures obtained in several cases, and it is only necessary to add that the lower part of the diagram refers to E.M.F. and efficiency of cells, and the upper part to the work done in lamps, and Curves I., II., and III. to that lost in the primary battery when arranged in one, two, and three groups.

BRITISH ASSOCIATION, 1886.

The following papers marked * were contributed to the late meeting of the British Association on various subjects connected with Electrolysis.

ON THE ACCURACY OF OHM'S LAW IN ELECTROLYTES.*

BY PROF. G. F. FITZGERALD, F.R.S., AND MR. TROUTON.

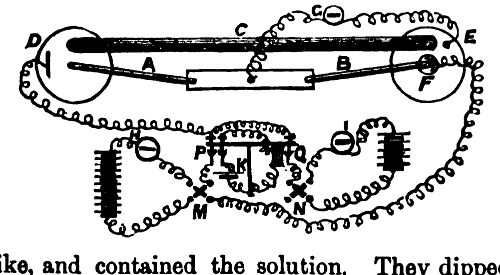
Some preliminary experiments were begun in the spring of this year, and have been carried on from time to time since, with a view to determining how far Ohm's law may be relied on in the case of electrolytes.

Though as yet no very high limits of accuracy in the experiments have been attained, owing to causes which will be later on explained, still it is hoped that from the experience already gained most of the difficulties have been got over, and that soon results of a much greater degree of accuracy will be arrived at.

The method adopted is that described in the British Association Report for Glasgow, 1876, which Prof. Chrystal, in connection with Clerk Maxwell, employed in the case of metal conductors, namely, that of a Wheatstone bridge, two of the arms of which are of about equal section and resistance, while the remaining two, though of equal resistance, are of very different sections. If Ohm's law be not true, the point of balance of the bridge varies with the amount of current passing through it. Balance having been obtained, the battery-power is altered, and if balance still subsists, the deviation from Ohm's law, if there be any, is such as cannot be detected with apparatus of the sensitiveness employed.

The great difficulty in experimenting in this way is that the change in the current alters the temperature of the two arms of unequal section very differently, and proportionately also their resistances. While the thick conductor alters little in temperature, the thin one alters considerably. Thus the point of balance is changed, even though Ohm's law be true. To avoid this effect it is necessary, having balanced with the large current, to immediately pass the smaller current before the temperature can sensibly alter. As this requirement is practically impossible to satisfactorily fulfil, the method employed is a rapid alternation of a large and small current. If Ohm's law be not true, a balance in this case can only be apparent, and on reversing the direction of one of them, the two currents, which before neutralised each other's action, now conspire to deflect the galvanometer. The mode of experimenting is to find balance with a large and a small battery alternately in circuit, and rapidly enough for the temperature during the smaller current to be sensibly the same as while the larger one is acting, then to change the direction of one of the currents and to again balance. The distance is observed between the two points of balancing, but if the bridge still balances it is assumed for the purposes of calculation that the distance is what the galvanometer employed only just detects. From this, from the two currents the section and resistance of the thin conductor, h is calculated where $e = rc(1 - hc^2)$, as is explained in the above-mentioned report.

The liquid, chosen for experimenting with, was a solution of copper sulphate in water. The equal arms consisted of two glass tubes bent at right angles at each end, A and B, arranged



syphon-like, and contained the solution. They dipped into a long narrow trough, as shown in the diagram. The arm of large section C, a tube 119cm. long and 2·38cm. in internal diameter, reached from the bowl D, into which the tube A also dipped, to the bowl E. The small arm was a hole ·055cm. in diameter, drilled in the side of the beaker F, ·062cm. in thickness, into which the tube B dipped.

The battery poles consisted of copper plates, one in the beaker, the other in the bowl D. The contact breaker was a T piece worked by an electromagnet and cell K, as shown in the diagram. One of the batteries contained ten Grove cells, the other five, and both could be thrown in circuit in either direction by means of the reversing keys M and N. By proper adjustment of the mercury cups P and Q one of the batteries went in circuit, just as the dipper on the other side, coming out of the mercury, threw the second battery out of circuit. By means of the galvanometers H and I it could be seen, during the course of an experiment, whether the contacts were working properly or not.

One of the copper wires leading to the galvanometer dipped into the bowl E, the other into the trough, and could be moved up and down it in order to obtain balance, the distance moved being read off a scale along the trough. There was always more or less of a permanent current through the galvanometer, even though the poles were both of copper; this, especially, as it was liable to sudden changes in amount, caused by moving the trough pole or by accidental shaking, necessitated the employment of the galvanometer in a comparatively insensitive condition. Various devices were tried with a view of avoiding this current, such as electroplating the poles, using chemically pure copper sulphate, or employing for poles either end of a broken wire, so as to have, if possible, metallically like poles. These were found to give an indication of current even in distilled water.

The resistance of the smaller arm was about 800 ohms, but owing to its smallness varied greatly with the current through the change of temperature. A good deal of trouble was experienced through the resistance of the smaller arm at times being less when the current passed in one direction than when it passed in the other. This occurred so often that until its cause was understood, and steps thus could be taken to prevent it, there was little hope of completing the experiments. After various attempts it was discovered to be due to the density of the solution on the outside of the beaker in the bowl being slightly different from that inside, so that the density in the hole, and consequently its resistance, depended on the direction of the current, the electric transfusion of the liquid always changing direction with the current.

A number of experiments were made of a more or less satisfactory nature; in all no difference in the position of balance was found on reversing one of the batteries. Taking the difference, then, to be what the galvanometer would just detect, h is calculated to be less than 10^{-4}. This is, of course, very large. The limit Prof. Chrystal reached in his experiments with metal conductors was less than 10^{-12}.

With a view to reaching a higher limit a smaller hole was next tried. It was ·17cm. in diameter drilled in a plate of glass ·022cm. thick. Its resistance was about 2,700 ohms, so that a longer tube had to be used for the large arm. The balance was always found to be very different when one of the batteries was changed in direction. However, this was probably entirely due to the difference in temperature during the small and large currents, for h calculated from this was not even as small as in the first experiments; also the difference between the balance points varied with the speed of the contact breaker. Unfortunately the contact breaker, which was adjustable in its rate of vibration, had reached its limit of speed, so that a completely new arrangement has now to be employed.

PROF. BOUTY ON ELECTROLYTIC CONDUCTIVITY.*

The author first describes Lippmann's method of measuring the resistance of electrolytes, viz., by tapping off and measuring the E.M.F. between two points of the liquid contained in a cylindrical tube, and comparing this with the E.M.F. tapped off a length of known wire included in the same battery circuit as the liquid. He proceeds to use it also for determining the polarisation of either electrode, by measuring the E.M.F. between one of the main electrodes supplying current to the liquid and one of the tapping electrodes; using the obvious relation

$$e = r\,C + p$$

in order to find p, the polarisation.

* Abstract by Oliver Lodge, made for the B.A. Committee on Electrolysis.

Digitized by Google

With platinum electrodes and acidulated water he thus reckons that with a current of average intensity of about $8 \times^{-8}$ amperes per square centimetre, the polarisation of the electrode rises as follows:—

	Polarisation of the cathode is	Polarisation of the anode is
In 5 minutes	·056 volt.	·103 volt.
„ 40 „	·063 „	·166 „
„ 60 „	·065 „	·175 „

He then applies a slightly stronger current, but as it is very variable I do not see that the numerical results obtained are much good. However, the idea is that the polarisation of the cathode attains a maximum and begins even to diminish, while that of the anode goes on increasing.

He then measures the resistance of acid water in a long siphon tube, and considers that it is independent of current intensity, and asserts: "*A liquid has only a single way of conducting electricity, whatever may be going on at the electrodes. The expressions 'metallic conductivity' and 'electrolytic conductivity' ought to disappear from science.*"

Electrolysis of Mixtures.

A number of mixed salts are tried, one of them being always a salt of copper. Results are given for the electrolysis with copper electrodes of a mixture of sulphate of copper and sulphate of zinc, saturated in the cold, and are analysed thus: "For current intensities from 5 to 12 ten-thousands of an ampere per square centimetre the polarisation of the anode is constant and equal to ·0088 volt; but that of the cathode varies enormously. For an intensity 2·9 (ten thousandths of an ampere as before) it is already ·02 volt; it increases slowly with the current and is sensibly constant for the same current when prolonged. But at an intensity 8·6 a new phenomenon is produced; polarisation increases with time, first very slowly, then more and more rapidly, going from ·04 to ·65 volt; at the same time one notices that the metallic and brilliant deposit of pure copper which one had hitherto obtained is displaced by a ruddy and non-adhesive deposit. In proportion as it is produced the polarisation increases, and the deposit overspreads the electrodes with increasing rapidity.

"Finally, augmenting the current still more, the deposit passes gradually from red to black, while polarisation increases in a continuous manner, and for a sufficient current intensity the deposit acquires anew a certain adherence. It is then dark grey, very rich in zinc, and recalls by its aspect deposits of zinc obtained from impure commercial sulphate of zinc.

"*As for the conductivity of the liquid it remains constant all the time, in spite of the variety of electrolytic actions,* to which a study of polarisation and aspect of deposit bear witness. . . . The same *kind* of thing happens with other proportions of $CuSO_4$ and $ZnSO_4$. . . .

"One may remark further that the specific resistance of the liquid passes through a minimum for a certain composition of the mixture; it is then inferior to the resistance of even a saturated solution of one of the salts, and *à fortiori* to that of the same salt diluted down to the strength in which it occurs in the liquor. *So the molecules of two mixed salts take part in the transport of electricity, even when only one of the two metals is deposited on the cathode.*"

All the variations of polarisation in the above case are then simply and naturally explained by the fact of exhaustion, in the liquid near cathode, of the salt of the metal being deposited, except in so far as diffusion replenishes it. With strong currents it is therefore plainly necessary for zinc to be deposited as well as copper, and it is equally obvious that this zinc will tend to clear itself off again by local action.

The author then goes on to observe that very similar complications occur even when only one salt is intended to be present. Thus pure $CuSO_4$ almost always contains a trace of acid, and accordingly, in its solution, hydrogen plays much the same part as zinc has done in the above described experiment. For feeble intensities copper alone is deposited, but for stronger currents the deposit is red and contains some oxide [?]. Hydrogenised copper forms with copper, in fact, local couples in which copper is the attacked element. Evolution of heat by local action has been proved by the use of thermometer electrodes.

Even if $CuSO_4$ contained no acid to start with, it would soon get some by electrolysis;† for the solution of anode is never exactly equal to deposit on cathode.

ON DIATHERMANCY AND ELECTROLYTIC CONDUCTIVITY.*

BY SHELFORD BIDWELL, ESQ., F.R.S.

The following is one of the questions suggested by Dr. Lodge for the consideration of the committee on electrolysis:— Is there any relation between optical opacity and electrolytic conductivity?

Assuming that "optical opacity" is included in the more comprehensive term "opacity to radiation," I have endeavoured to ascertain experimentally whether those electrolytes which transmit radiation with the greatest facility, as evidenced by the effect produced upon a thermopile, are also the worst conductors of electricity. I may say at once that this was undoubtedly not the fact, and the relation which was supposed to be possible does not exist.

Considerable time and care were bestowed upon the experiments, and every precaution was taken with the view of ensuring accuracy. The thermopile used was a delicate one, containing 54 bismuth-antimony pairs; it was enclosed in a flannel-covered box, fitted with a pane of glass 1·5mm. thick opposite the face of the pile. The galvanometer was an astatic reflecting instrument of ·545 ohm resistance made by Elliott. The source of radiation was a small paraffin lamp, having a glass chimney about 2mm. thick.

The parallel glass sides of the cells, used to contain the liquids, were 13mm. apart, and 1·9mm. in thickness. A screen, with a small aperture, which could be instantly opened or closed by a sliding shutter, was interposed between the cell in use and the lamp. The various solutions were in every case exposed to radiation for a period of 30 seconds, and each observation was checked and standardised by the aid of a certain cell containing water. It is hardly necessary to describe the arrangements and method of observation in greater detail.

A few of the results, which, for the most part, need no comment, are given in the following table:—

Solutions, &c.	Diathermancy.
Empty cell	1,000
Water distilled	197
„ from tap	200
Alum, saturated solution	204
Ammonium chloride solution	215
Zinc sulphate sol. sp. gr. 1·157	207
Sulph. acid 1·032 (5 per cent.)	208
„ „ 1·225 (30 „)	216
„ „ 1·638 (72 „)	292

The observations with sulphuric acid are the most instructive. It is well known that the electrical conductivity of sulphuric acid at first increases with the concentration, reaching a maximum when the strength of the solution is about 30 per cent., and afterwards rapidly diminishing. That there is no corresponding minimum diathermancy appears clearly enough from the above table, which seems to furnish a conclusive answer in the negative to the question proposed.

The diathermancy of a solution of zinc sulphate was almost independent of its strength, being nearly the same for a 5 per cent. as for a saturated solution. It was quited unaffected by the passage through the solution of a strong battery current.

THE METROPOLITAN BOARD OF WORKS AND OVERHEAD TELEGRAPH WIRES.

We are glad to observe that the METROPOLITAN BOARD OF WORKS has not allowed to drop out of notice the question of overhead telegraph wires in the Metropolis. The Works and General Purposes Committee have made their report, after a prolonged inquiry, which was ordered to be instituted last January; and although a Committee of the House of Commons meanwhile has reported in a sense rather favouring non-interference, the chief governing body of London has resolved not to slacken its efforts for the better regulation and consequent abatement of a peril and nuisance which, but for the peculiar circumstances of the case, would never have been permitted to arise. The overhead wire system came into being without protest, and secured a footing for many years, because nobody could foresee the sudden and gigantic extension which it actually underwent in consequence of the invention of the telephone. Proceeding on the established assumption that nobody's leave to erect wires need be asked except the owners of houses to which they had to be affixed, the Companies pushed on their operations unchecked, until interference would have seemed arbitrary or confiscatory; and they have enlisted public convenience on their side to such an extent that it has become almost impossible to check them without doing their customers a great disservice.

Taking advantage of the legal uncertainties which surround the question, the Companies have made a point of thickening their network of wires and of carrying them in every possible direction, so as to create a precedent for every conceivable step which their business may some day require. No edifice has been too sacred for them to invade, and no thoroughfare too crowded for them to imperil. The more incongruous the connection between wires and structure the better the companies like it; and wherever a busy street has to be crossed the angle adopted invariably threatens the greatest number of people. Observing these things, an unreflecting public is apt to say they have done their worst. This is precisely what the Companies desire should be said, and they have lost no time about it. But for these exceptional features of the case we should be disposed to echo the reformist's impatient cry—Why should London wait? We see, however, quite plainly why London has to wait for this particular reform; and are almost as much surprised as pleased that the METROPOLITAN BOARD OF WORKS perseveres in its efforts to put the wires under proper legal control. We know of only one restriction to which the companies are at present liable. It is stated that they complain of the Post Office, where it retains control over wires running by the side of the railroads, refusing permission for telephone wires to cross the lines overhead. If this is true, the prohibition must be due solely to there being somebody who has power to protect passengers travelling in railway trains—a protection which does not exist for the protection of passengers travelling on foot.

It has been generally asserted by the defenders of the overhead wire system that its dangers have been much exaggerated; and, if we mistake not, this is a view of the question countenanced by some authorities of the Post Office. The Post Office can speak for itself with confidence, no doubt; its overhead wires are comparatively few in number, and we believe are decreasing rather than increasing. They are probably as securely erected as work done by a responsible State Department ought to be, and we may be sure that neither the position nor the numbers of its wires will provoke any public outcry. Still, the Post Office owns a good many overhead wires in the metropolis, besides having possibly in view the prospective ownership of all the other wires. This may account for the lukewarmness displayed in that quarter when proposals are being made to get our urban telegraph systems put under ground. But it is scarcely fair to the public to lend a high authority to the statement that there is little or no danger from overhead wires. The experience of last winter afforded ample proofs of the contrary. If few people were maimed or killed by the wreckage of falling wires during the great storm, it was a marvel of mercy, not an evidence of security. A house may fall without hurting anybody, but that is not a reason for neglecting the inspection of buildings; and although a telegraph wire is not so certain to do injury if it fall as the wall of a badly built house, it is far more likely to fall; and, unlike the house, the older it is the more dangerous it becomes. The danger we refer to has multiplied ten thousand times in the streets of London during the past five or six years, and goes on increasing at an alarming rate. It is possible to exaggerate the accidents due to falling telegraph wires, but one can hardly exaggerate the risks we are needlessly incurring by their indiscriminate erection. The action of the Post Office referred to above is taken, no doubt, for the safety of their own wires; but human life is quite as valuable as Post Office wire, and runs far greater risks from telephone wires crossing the streets of a busy town.

Digitized by Google

About one ground of objection to the increasing network of wires which is rapidly enclosing this great city there can be no exaggeration. Utility may, and does, reconcile us to many unsightly objects both in town and country life; and when the disfigurement is a necessity we have only to grin and bear it. But in this relation the constant aim of *The Electrician* has been to inform the public that the disfigurement complained of is not a necessity; that, on the contrary, it could have been easily avoided by a little foresight on the part of the local authorities, and a little prudence on that of the offending Telephone Companies. Even now it would be cheaper to commence laying wires underground than to postpone the operation indefinitely. Obviously, it will have to be done sooner or later. The burden of the wires will within measureable distance of time become unbearable, even if the offence against public taste be still condoned. That the nuisance should be endured so long can only be explained by popular ignorance of the problem to be solved. All sorts of misleading statements are made current as to the expense of laying wires in underground channels, and the difficulty of maintaining them in working order. The experience of the Post Office's underground system, which is of considerable extent, and the results of trials already made in America, are conclusive on both these points. We have no hesitation in saying that in the long run the underground system, at all events in populous towns, is cheaper and more efficient than any overhead system can possibly be, and has the permanent advantage of exciting no opposition either on the score of bodily danger or æsthetic offence. We are certain that public taste will not long permit the best architecture of the most variedly picturesque city in the world to be wantonly disfigured when the fact becomes known that, without any substantial injustice, the Companies could be forced to lay their wires out of sight. Nobody desires to see the offending parties suffer for the neglect of the parish authorities or the uncertainties of the law; but when these have been strictly defined, as we may hope will now soon be done, there can be no longer any excuse for that defiance of public opinion which has characterised the proceedings of Telephone Companies ever since they started business.

CORRESPONDENCE.

THE CHARACTERISTICS OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: From the report in your issue of November 12, p. 20, I have become acquainted with Mr. Kapp's recent paper before the Society of Telegraph-Engineers and Electricians; and I desire, with your permission, to make a few remarks on it.

The main point of the paper is the estimation of the magnetic resistance of a magnetic circuit, as made up of the metallic resistances involved, plus the resistance of the air spaces, and it appears that this was published by Mr. Kapp about a year ago.

I think I ought to claim for myself that I believe I was the first to propose this method. I am far from wishing to say that Mr. Kapp has taken his work from me.

In a paper presented to the Royal Society on December 20, 1882, "On a Uniform Rotation Machine, and on the Theory of Electro-magnetic Tuning Forks," I developed a theory of magnetic circuits having substantially the same outline as that above stated. For abstract see *Proc.* R S., XXXIV., 445.

The same point of view was treated in some detail by Rowland in an address to the Congress of Electricians at Philadelphia, reported in your issue of Oct. 18, 1884, and following numbers. The report is somewhat imperfect; and in commenting on the subject (*Electrician*, XIV., 292), I said that it was necessary to wait for a fuller report. Unfortunately, I had got it into my head that it was a British Association Address, and so missed it. The paper would undoubtedly be worth your reprinting in full, if you can procure it.

As to Mr. Kapp's discussion of the law of magnetisation, I have been long engaged in experiments with a view to clearing this up. The ultimate completion of these is still far off. But I hope shortly to make use of certain completed results to give a partial discussion on general grounds in the *Phil. Mag.*

One more point. The statements as to saturation on page 21 of report of Mr. Kapp's paper are strange. The units employed are a terror. The mixing up of inches with C.-G.-S. at this time of day is really to be deprecated. However, I think I see what is meant, and have reduced his numbers to C.-G.-S. inductions, so as to be directly comparable with Rowland's and my results. I am not acquainted with Mr. Hopkinson's, but shall be surprised if they differ much from ours.

It appears from these numbers that the comments of Mr. Kapp, to the effect that his saturation numbers are higher than ours, are not at all justified, as far as wrought iron is concerned. On the contrary, his number for wrought iron is approximately the same as the number attained by Rowland, and much less than many of the numbers I have attained.

Mr. Kapp's numbers for charcoal iron are no doubt much greater than Rowland's or my highest numbers for charcoal rings. But I am curious to know how Mr. Kapp measured the magnetised sections in his wires and discs—a matter which seems to me of the greatest difficulty.

I should notice that such experiments as are available, other than Mr. Kapp's, place the saturation field of charcoal iron at about the same value as that of ordinary wrought iron. The advantage of charcoal iron is in the region of maximum permeability ($\mathfrak{B} = 5{,}000$ to $10{,}000$); here the permeability is enormous, as we find by measures of rings. But in the saturation region it is not a bit better than ordinary wrought iron.

As I have frequently noticed in recent papers, the saturation field in the equatorial sections of magnets with ends (bars) can be forced up very much higher than in rings of the same material.

I append a table of the chief saturation numbers attained by Mr. Kapp, Rowland, and myself, together with my calculation of Mr. Kapp's numbers, this last for your own satisfaction.

[For calculation of Kapp's numbers see below.]

WROUGHT IRON.

		Observed Highest $\mathfrak{B}$.
Kapp	Field magnets "18 lines"	16,740
Rowland	Ring, *Phil. Mag.* XLVI. (1875) 151	16,600
Bosanquet	Ring E, *Phil. Mag.* XIX. (1885) 76	17,245
"	Ring F	18,834
"	I (Lowmoor)	19,303
"	Bar. I., *Phil. Mag.* XVII. (1884) 532	19,650
"	Bar. II.	21,428
"	Plain Bar. I.,* *Phil. Mag.*, Sept., 1886, p. 300	29,388
"	Plain Bar. II.*	27,688

CHARCOAL IRON.

Kapp	Armatures, wire, "25 lines"	23,250
"	Armatures, discs, "22 lines"	20,460
Rowland	Ring, *Phil. Mag.* XLVI. (1873) 153	16,850
Bosanquet	Ring, *Phil. Mag.* XX. (1885) 321 ...	18,146
"	Ring	18,277

* The reference is to the description of the bars. The actual observations are not there given, such use of them only being made as is required for the purposes of the paper. The two bars came from the same piece of iron.

—Yours, &c., R. H. M. BOSANQUET.

S. John's College, Oxford.

Reduction of Mr. Kapp's saturation values in "lines of force" (*The Electrician*, November 12th, 1883, p. 21) to $\mathfrak{B}$ (C.-G.-S.),

2·54 centimetres = 1 inch.

$$\begin{array}{r} \log 2{\cdot}54 = {\cdot}40483 \\ 2 \\ \hline {\cdot}80966 \end{array} = \text{log. sq. centimetres per sq. inch.}$$

A field of 6,000 units C.-G.-S. is taken for "unit line of force."

$$\therefore \text{C.-G.-S. field is "lines of force"} \frac{\times 6000}{\text{sq. cents. per sq. inch}}$$

log 6,000 = 3·77815
log cents. per sq. inch = ·80966
2·96849 = log factor 930·01.

"Lines of Force."

log 25 = 1·39794		
2·96849		B
4·36643 = log		23,250
log 22 = 1·34242		
2·96849		
4·31091 = log		20,460
log 18 = 1·25527		
2·96849		
4·22376 = log		16,740

Rowland's Q's are divided by 10 to reduce to C.-G.-S., as he worked on the metre-gramme-second system.

SECONDARY BATTERY PLATES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the correspondence columns of your last issue attention is called to a patent specification, No. 8540, 1885, with reference to the form of secondary battery plates lately put forward somewhat prominently by Mr. P. Gadot, of Paris, the form and arrangement claimed being lead plates with conical perforations, packed with oxide of lead, and fixed face to face, so as to retain the active material in position.

I would mention that in my specification, No. 3926, September 10, 1881, I fully describe and illustrate the fixing together of two packed perforated plates, and in a later specification, No. 2818, June 15, 1882, the use of conical and other suitably formed perforations for keeping in or retaining the active material.

Such double plates were experimented upon by me in 1881-2, but they have some obvious disadvantages both in their primary manufacture, cost, and subsequent use.

With regard to the attachment of the active material to the ordinary *single* grid plates, if well made and properly treated, no difficulty occurs, the falling out of the solid cones or squares of peroxide of lead arising only when bad workmanship or usage come into play. I have had such plates in continuous use for more than four years, from which not a single plug of active material has become detached or loosened.
—Yours, &c., JOHN A. SELLON.

Sydenham Hall, November 15th, 1886.

SUNDAY AT OUR POST OFFICES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On the occasion of the election of mayors for the cities and towns of the United Kingdom yesterday many graceful allusions were made to the fact that during this year's mayoralty the Sovereign would complete the fiftieth or Jubilee year of her reign. Such an event is rare in the history of any country, and since the year 827—1,060 years ago—it has happened in this country only on three occasions. Henry III. completed the fiftieth year of his reign in 1266, Edward III. in 1377, George III. in 1810.

How Her Majesty's subjects may best celebrate the Jubilee of their Queen is a question which is receiving much attention. Various suggestions have been made, and no doubt every town and village will take part in the rejoicings, and in most cases accomplish some object which shall fitly commemorate the event, and substantially benefit the community.

In connection with this remarkable occurrence I should like to appeal to every person in the kingdom on behalf of the vast army of Post Office *employés* throughout the provinces whose onerous duties deprive them of the day of rest. I feel sure that all thoughtful and considerate people will agree with me that the time has arrived when the performance of unnecessary Sunday duty at the post offices may be altogether dispensed with.

Just fifty years will have expired next year since Dr. Wheatstone invented the electric telegraph system, which now spreads itself like a network over all the land, reaching every town and almost every village, and which enables us to have instant communication with each other in any part of the British Isles for the small fee of sixpence.

Three years after Her Majesty's accession, and two years after her coronation, viz., in 1840, Mr. Rowland Hill succeeded in obtaining parliamentary sanction to the introduction of his penny postage system, which has conferred inestimable advantages and blessings on the country at large. In 1855 the repeal of what have been called the "taxes on knowledge," viz., the newspaper stamp, the advertisement duty, and the excise duty on paper was brought about through the exertions of Mr. Thomas Milner Gibson, at that time the colleague of Mr. John Bright in the representation of this city.

Since 1870 we have been enabled to send post cards, circulars, and newspapers at the cost of a halfpenny.

The money order and postal order system, the annuity system, the Post Office Savings Bank, the Registered Letter Department, and the Parcels Post, have all been established during the reign of Queen Victoria.

It is remarkable that in the face of all the Post Office reforms which have been instituted within the last fifty years, there still exists a custom unworthy of the present age of progress, viz., the practice of employing in the provincial post offices large numbers of men and women in the performance of Sunday duties, which are regarded as unnecessary, and never have been performed in the metropolis.

Although London is the most populous and the greatest commercial city in the world, there has never been a Sunday delivery of letters there. If the 4,000,000 residents in the metropolis, and the thousands of visitors and strangers who are always to be found there, can, without inconvenience, dispense with the receipt and despatch of letters on Sundays, can there be any legitimate reason why the provinces should not be placed upon the same footing?

The question was argued in the House of Commons 36 years ago, and by a large majority it was resolved to abolish Sunday labour at all provincial post offices. An agitation was afterwards got up against this reform, and Lord John Russell, then the head of the Government, yielded to the pressure thus brought to bear.

But whatever arguments might be used then as to the inconvenience of the public in cases of emergency, they have no force to-day. We have, as I have said, facilities for communicating by telegraph which did not then exist.

Again, commercial travellers, who in consequence of the dearness and slowness of railway travelling thirty-six years ago were obliged to remain "on circuit" over the week end, are able to reach home on Saturday at small cost, and in a very short time. Since, therefore, they now spend their Sundays at home with their families they have no longer any need for the Sunday post.

At the time I speak of many merchants lived in the towns on or near their business premises. Now they live in the suburbs or in country places, and do not care to have letters delivered on Sundays. In many instances the Post Office authorities are requested *not* to deliver on that day. In other cases, where letters are taken out by the letter carriers on Sunday, they cannot be delivered for the reason that many people are absent from their houses, and also that places of business are closed.

The number of people employed at the post offices of the United Kingdom is close upon 100,000, a very large proportion of whom are employed during the Sunday in doing work which I am sure can be dispensed with.

A little consideration for these useful and industrious public servants, and a small personal sacrifice on the part of the public, would lead to the total abolition of Sunday labour at the Post Office, excepting in the Telegraph Department, and even this would be reduced, as the inclination to send telegrams is very frequently occasioned by the receipt of business letters.

Digitized by Google

If the Jubilee year of the reign of the Queen should be signalised by the legislative prohibition of Sunday deliveries and despatches of letters, it will ever be memorable as being associated with a most beneficent and much needed reform.

Should any excuse be needed for this public appeal from one not immediately interested in the Post Office, it will be found in the fact that by the regulation of the Department letter carriers and others are forbidden to agitate for any cessation or reduction of Sunday labour.—Yours, &c.,

ELLIS LEVER, F.S.S.

Manchester, November 10, 1886.

NEW ZEALAND CABLES.

The following is a reference by the London correspondent of the *Manchester Guardian* to the questions under discussion between the Eastern Extension Telegraph Company and the New Zealand authorities. We have reason to believe that this statement gives correctly the latest phase of the discussion :—

"Since I referred some days ago to the dispute between the Eastern Extension Telegraph Company and the Government of New Zealand the quarrel has assumed a new aspect. The Government of New South Wales and Victoria showed their disapproval of the attitude of Sir Julius Vogel by refusing to collect the New Zealand terminal charges levied in Australia before the despatch of cable messages, and this week there was a prospect of the cable service coming to a standstill. Yielding to the suggestion of Sir Dillon Bell the Agent-General of New Zealand, the Extension Company have decided to withdraw their new tariff, to impose the old charges without any subvention, and to give lower press rates till the whole question can be settled by the New Zealand Parliament This concession at any rate shows the desire of the Extension Company to consult the public interest."

M. DEPREZ ON THE EXPERIMENTS OF M. FONTAINE.

At the meeting of the *Academie de Sciences*, held on the 2nd inst., the following note was read by M. Deprez :—M. Fontaine has lately submitted to the Academy an experiment on the transmission of power by electricity, by means of a process which he considers novel, and which consists in substituting for the generating and the recipient machines a collection of machines connected in series, and in such a number that the sum of their electromotive forces makes up the value which it is desired to obtain. In the experiment in question the number of generators was four, and the number of the recipients three. This idea is far from novel, and it has been proposed by all the electricians who have sought to obtain high tensions without having recourse to the construction of the special machines which I have been the first to realise.

As for the method employed by M. Fontaine to govern simultaneously the four rings of the generators, it much resembles that described in a patent which I took out on April 28th, 1885, in which I gave precisely an example of the application of this procedure to a machine with four rings of 0·30 metre in diameter and 0·20 metre in length like those of the machine which served for the experiments in the works of the Northern of France Railway in February, 1883. There was thus produced an apparatus, each ring of which could give a force of 1,500 volts at 1,000 turns per minute, the internal resistance of a ring being 5·5 ohms, and the total resistance of the four inducers being 15 ohms. The weight of the acting parts was composed of :—

Soft iron	1,124 kilos.
Copper	652 „
Total	1,776 „

On adding 600 kilos. for the support, it will be seen that we had arrived at a total weight below 2,500 kilos. for a machine with four rings capable of producing 6,000 volts and 10 amperes at the speed of 1,000 turns per minute. This is half the weight of M. Fontaine's four machines. These results admit of no doubt, since they are obtained by the addition of the effects of identical machines perfectly known.

But this project was not continued, because the conditions laid down for the experiments at Creil were quite different. The machines of M. Fontaine revolved at the speed of 1,300 turns per minute ; those at Creil made only 500 turns in the same time. The linear speed of the rings of M. Fontaine is 20·5 metres per second, as against 7·5 metres for those at Creil. If I had given the latter a linear speed of 20·5 metres they would have yielded an electromotive force exceeding 16,000 volts. The conditions are in no manner comparable, as it will be seen, and if the Creil machines are heavy it is simply because only a very low speed is required of them, and nothing has been done to lighten them. If in the arts we were to compare machines among themselves, taking lightness as the main condition, the engines of torpedo boats would be far superior to those in factories, and yet the use of the latter is far more general, though they are much heavier per unit of power. The reasons for this preference are too evident to require explaining.

In this order of ideas M. Fontaine's expedient is the same as that of the manager of a factory, who, instead of a single engine of 100 horse-power, moving slowly and surely, should prefer to employ four small engines of 25 horse-power each, moving at a very high speed, and acting upon the same shaft by means of mechanical transmission, having for their object the reduction of the speed.

M. Cabenallas said a few words in justification of the plan of using several machines connected in series, in preference to one large machine.

At the next meeting of the Academie, on Nov. 8, M. Fontaine replied to M. Deprez's criticisms categorically, as follows :—

1. The plan of coupling several machines in series to obtain a higher tension was first described by M. Gramme in 1872, and in our note nothing is said which could lead to the supposition that we thought the idea to be novel.

2. The means by which the four generators are simultaneously regulated, were first described and employed by MM. Celosétien et Félix, in 1879. If M. Deprez has taken out a patent for the arrangement in 1885, no doubt he was in ignorance of this anticipation.

3. We did not in our note institute any comparison between our own experiments and those at Creil, but it would be easy to show that the speed of our machines cannot be considered excessive, since there are actually in existence more than 1,000 Gramme machines, which have been running at the same speed for the last 10 years without needing repair.

Our only claim to novelty lies in the thoroughly practical character of the results which we have shown. Never, until now has 50 horse-power been transmitted through a resistance of 100 ohms, with a return of 52 per cent., by means of dynamo machinery weighing altogether not more than 8,400 kilogrammes, and costing only 16,450fr.

If, in practice, it is usual to prefer one large engine running at a slow speed to several smaller engines running more quickly, this is chiefly in order to realise an economy of fuel. M. Deprez's comparison is not, therefore, a happy one, since with his heavy machines he has not obtained a return of more than 44 per cent., while we have obtained a decidedly higher efficiency.

DYNAMO-ELECTRIC MACHINERY.*

BY J. HOPKINSON, M.A., D.Sc., F.R.S., AND E. HOPKINSON, M.A., D.Sc.

Theoretical Construction of Characteristic Curve.

Omitting the inductive effects of the current in the armature itself, all the properties of a dynamo machine are most conveniently deduced from a statement of the relation between the magnetic field and the magnetising force required to produce that field, or, which comes to the same thing, but more frequently used in practice, the relation between the electromotive force of the machine at a stated speed and the current around the magnets. This relation given, it is easy to deduce what the result will be in all employments of the machine, whether as a motor or to produce a current through resistance, through an electric arc, or in charging accumulators ; also the result of varying the winding of the machine, whether in the arma-

Digitized by Google

ture or magnets. The proper independent variable to choose for discussing the effect of a dynamo machine is the current around the magnets, and the primary relation it is necessary to know concerning the machine is the relation of the electromotive force of the armature to the magnet current. This primary relation may be expressed by a curve (Hopkinson Mechan. Engin. Instit. *Proc.*, 1879, pp. 246 *et seq.*, 1880, p. 266), now called the characteristic of the machine, and all consequences deduced therefrom graphically ; or it may be expressed by stating the E.M.F. as an empirical function of the magnetising current. Many such empirical formulæ have been proposed ; as an instance we may mention that known as Fröhlich's, according to whom, if c be the current in the magnets, E the resulting E.M.F., $E = \frac{a c}{1 + b c}$. For some machines this formulæ is said to express observed results fairly accurately, but in our experience it does not sufficiently approximate to a straight line in the part of the curve near the origin. The character of the error in Fröhlich's formula is apparent by reference to curves in Diagram A, which gives a series of observations on a dynamo machine, and for comparison therewith a hyperbola F, drawn as favourably as possible to accord with the observations.* Such empirical formulæ possess no advantage over the graphical method aided by algebraic processes, and tend to mask much that is of importance.

One purpose of the present investigation is to give an approximately complete construction of the characteristic curve of a dynamo of given form from the ordinary laws of electro-magnetism and the known properties of iron, and to compare the result of such construction with the actual characteristic of the machine. The laws of electro-magnetism needed are simply (Thomson, papers on "Electrostatics and Magnetism;" Maxwell, "Electricity and Magnetism," Vol. 2, pp. 24, 26, and 143), (1) that the line integral of magnetic force around any closed curve, whether in iron, in air, or in both, is equal to $4 \pi n c$ where c is the current passing through the closed curve, and n is the number of times it passes through ; (2) the solenoidal condition for magnetic induction—that is, if the lines of force or of induction be supposed drawn, then the induction through any tube of induction is the same for every section. Regarding the iron itself, we require to know from experiments on the material in any shape the relations between α, the induction, and a, the magnetic force at any point ; for convenience write $a = f^{-1}(\alpha)$, or $\alpha = f(a)$. From these premises, without any further assumption, it is easy to see that a sufficiently powerful and laborious analysis would be capable of deducing the characteristic of any dynamo to any desired degree of accuracy. This we do not attempt, as even, if successful, the analysis would not be likely to throw any useful light on the practical problem. We shall calculate the characteristic, first making certain assumptions to simplify matters. We shall next point out the nature of the errors introduced by these assumptions, and make certain small corrections in the method to account for these sources of error, merely proving that the amount of these corrections is probable, or deducing it from a separate experiment, and again compare the theoretical and the actual characteristic.

First Approximation.—Assume that by some miracle the tubes of magnetic induction are entirely confined to the iron, excepting that they pass directly across from the bored faces of the pole-pieces to the cylindrical face of the armature core. This, we shall find, introduces minor sources of error, affecting different parts of the charcteristic curve to a material extent. Let I be total induction through the armature, A_1 the area of section of the iron of the armature, l_1 the mean length of lines of force in the armature, A_2 the area of each of the two spaces between core of armature and the pole-pieces of the magnets, l_2 the distance between the core and the pole-piece, A_3 the area of core of magnet, l_3 the total length of the magnets. All the tubes of induction which pass through the armature pass through the space A_2 and the magnet cores, and by our assumption there are no others. We now assume further that these tubes are uniformly distributed over these areas. The induction per square centimetre is then $\frac{I}{A_1}$ in the armature core, $\frac{I}{A_2}$ in the non-magnetic spaces, $\frac{I}{A_3}$ in the magnetic cores ; the corresponding magnetic forces per centimetre linear must be $f\left(\frac{I}{A_1}\right)$, $\frac{I}{A_2}$, $f\left(\frac{I}{A_3}\right)$. The line integral of magnetic force round a closed curve must be $l_1 f\left(\frac{I}{A_1}\right) + 2\, l_2 \frac{I}{A_2} + l_3 f\left(\frac{I}{A_3}\right)$. In this approximation we neglect the force required to magnetise pole-pieces and

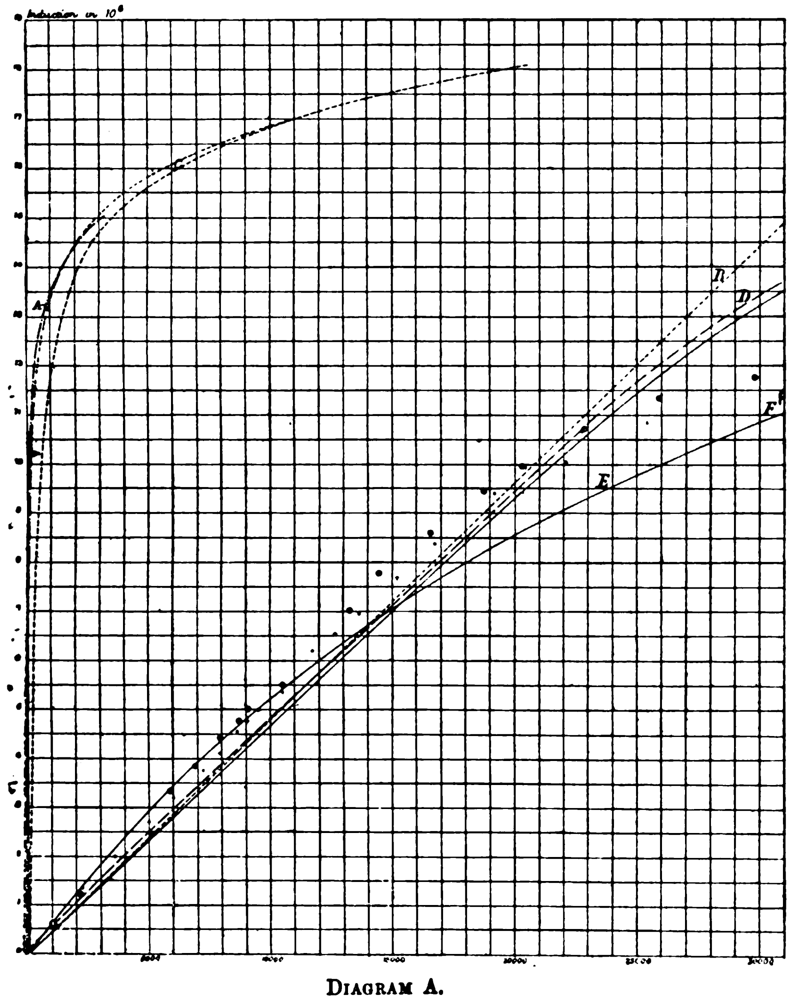

DIAGRAM A.

Approximate Synthesis of characteristic curve :—A, armature. B, air space. C, magnets. D, deduced curve. E, observed results, + ascending, (+) descending. F, Frohlich's curve.

[* Added August 17th.—That Frölich's formula cannot be a thoroughly satisfactory expression of the characteristic of a dynamo machine is evident from the consideration that E should simply change its sign with c, that is, be an odd function of c. There should be a point of inflexion in the characteristic curve at the origin. Another empirical formula $\frac{E}{a} = \tan^{-1}\frac{c}{b}$ is free from this objection, but still fails to fully represent the approximation of the curve to a straight line on either side of the origin, and it is equally uninstructive with any other purely empirical formula.]

Digitized by Google

other parts not within the magnet coils to avoid complication. The equation of the characteristic curve is then $4\pi n c = l_1 f\left(\frac{I}{A_1}\right) + 2 l_2 \frac{I}{A_2} + l_3 f\left(\frac{I}{A_3}\right)$. This curve is, of course, readily constructed graphically from the magnetic property of the material expressed by the curve $a = f(a)$. In Diag. A curve A represents $x = l_1 f\left(\frac{y}{A_1}\right)$, the straight line B $x = 2 l_2 \frac{y}{A_2}$, curve C $x = l_3 f\left(\frac{y}{A_3}\right)$, and curve D the calculated characteristic. When we compare this with an actual characteristic E, we shall see that, broadly speaking, it deviates from truth in two respects :—(1) It does not rise sufficiently rapidly at first; (2) it attains a higher maximum than is actually realised. Let us examine these errors in detail.

(1) The angle the characteristic makes with the axis of abscissæ near the origin is mainly determined by the line B. We have, in fact, a very

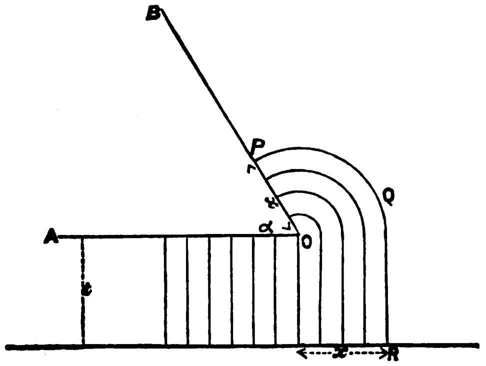

Fig. 1.

considerable extension of the area of the field beyond that which lies under the bored face of the pole-piece. The following consideration will show that the extension may be considerable. Imagine an infinite plane slab, and parallel with it a second slab cut off by a second plane making an angle a. We want a rough idea of the extension of the area between the plates by the spreading of the lines of induction beyond the boundary. We know that the actual extension of the area will be greater than we shall calculate it to be if we prescribe an arbitrary distribution of lines of force other than that which is consistent with Laplace's equation.

Assume, then, the lines of force to be segments of circles centre O, and straight lines perpendicular to O A. The induction along a line P Q R will be $\frac{V}{(\pi - a)x + t}$, V being difference of potential between the planes, and the added induction from O P B will be

$$\int_0^x \frac{V\,dx}{(\pi - a)x + t} = \frac{V}{\pi - a} \log \frac{(\pi - a)x + t}{t}.$$

Thus if $a = \frac{\pi}{2}$ we have for $x = t, 2t$, &c.

x	$\frac{1}{\pi - a} \log \frac{(\pi - a)x + t}{t}$		
t	·599	$3t$	1·190
$2t$	·904	$4t$	1·263
		$5t$	1·387
		$10t$	1·792

showing that the extension of the area of the field is likely to be considerable.

(2) The failure of the actual curve to reach the maximum indicated by approximate theory is because the theory assumes that all tubes of induction passing through the magnets pass also through the armature. Familiar observations round the pole pieces of the magnets show that this is not the case. If ν be the ratio of the total induction through the magnets to the induction in the armature we must, in our expression for the line integral of magnetising force, replace the term $f\left(\frac{I}{A_3}\right)$ by $f\left(\frac{\nu}{A_3}\right)$; ν is not strictly a constant, as we shall see later; it is somewhat increased as I increases owing to magnetisation of the core of the armature, and it is also affected by the current in the armature. For our present purpose we treat it as constant.

There is yet another source of error which it is necessary to examine. Some part of the induction in the armature may pass through the shaft instead of through the iron plates. An idea of the amount of this disturbance may be readily obtained. Consider the closed curve ABCDEF, AB and FEDC are drawn along lines of force, AF and BC are orthogonal to lines of force. Since this closed curve has no currents passing through it, the line integral of force around it is *nil*; therefore, neglecting force along ED, we have force along AB is equal to force along FE and DC. In the machine presently described we may safely neglect the induction through the shaft; the error is comparable with the uncertainty as to the value of l_1; but in another machine, with magnets of much greater section, the effect of the shaft would become very sensible when the core is practically saturated.

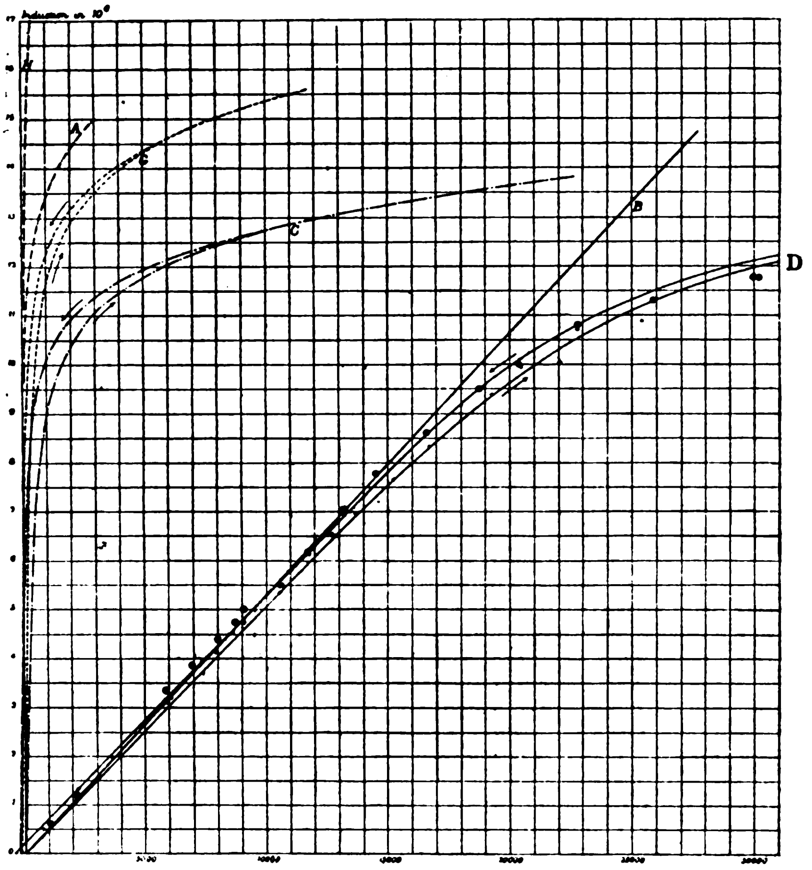

Diagram B.

Correct Synthesis of characteristic curve :—A, armature. B, air space. C, magnets. D, calculated curve. E, observations, + ascending, (+) descending. G, yoke. H, pole pieces.

The amended formula now becomes.

$$4\pi n c = l_1 f\left(\frac{I}{A_1}\right) + 2 l_2 \frac{I}{A_2} + l_3 f\left(\frac{I}{A_3}\right) + l_4 f\left(\frac{\nu I}{A_4}\right) + 2 l_5 f\left(\frac{I}{A_5}\right)$$

where l_4 is the mean length of lines of force in the wrought iron yoke, A_4 the area of the yoke, l_5 and A_5 corresponding quantities for the pole-pieces, the last two terms being introduced for the forces required to magnetise the yoke and the two pole-pieces.

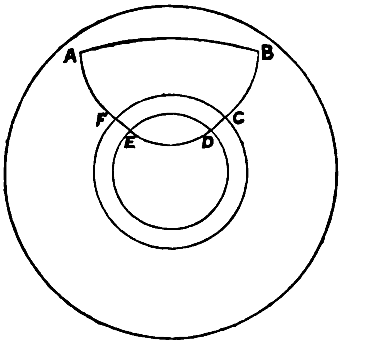

Fig. 2.

We now repeat the graphical method of construction exactly as before, the actual observations of induction in armature and current being plotted on the same diagram, (Diagram B), in which curve G represents the force required to magnetise the yoke, and curve H that required to magnetise the pole-pieces. Before discussing these curves further, and comparing the results with those of actual observation, it may be convenient to describe the machine upon which the experiments have been made, confining the description strictly to so much as is pertinent to our present inquiry.

Description of Machine.

The dynamo has a single magnetic circuit, consisting of two vertical limbs, extended at their lower extremities to form the pole pieces, and having their upper extremities connected by a yoke of rectangular section. Each limb, together with its pole piece, is formed of a single forging of wrought iron. These forgings, as also that for the yoke, are built up of hammered scrap and afterwards carefully annealed, and have a magnetic permeability but little inferior to the best Swedish charcoal iron. The yoke is held to the limbs by two bolts, the surfaces of contact being truly planed. In section the limb is oblong, with the corners rounded in order to facilitate the winding of the magnetising coils. A zinc base, bolted to the bed-plate of the machine, supports the pole pieces.

The magnetising coils are wound directly on the limbs, and consist of 11 layers on each limb of copper wire 2·413 mms. diameter (No. 13, B.W.G.), making 3,260 convolutions in all, the total length being approximately 4,570 metres. The pole-pieces are bored to receive the armature, leaving a gap above and below, subtending an angle of 51 deg. at the centre of the fields. The opposing surfaces of the gap are 8mms. deep.

The following table gives the leading dimensions of the machine :—

	cms.		cms.
Length of magnet limb	=45·7	Distance between centres of limbs	=38·1
Width of magnet limb	=22·1	Depth of pole piece	=25·4
Breadth of magnet limb......	=44·45	Width of pole piece measured parallel to the shaft	=48·3
Length of yoke..................	=61·6	Thickness of zinc base	=12·7
Width of yoke..................	=48·3	Width of gap.....................	=12·7
Depth of yoke	=23 2		
Bore of fields..........	=27·5		

The armature is built up of about 1,000 iron plates, insulated one from another by sheets of paper, and held between two end plates, one of which is secured by a washer shrunk on to the shaft, and the other by a nut and lock-nut screwed on the shaft itself. The plates are cut from sheets of soft iron, having probably about the same magnetic permeability as the magnet cores. The shaft is of Bessemer steel, and is insulated before the plates are threaded on.

The following table gives the leading dimensions of the armature :—

Diameter of core	=24·5	Length of core over the end plates	=50·8
Diameter of internal hole ..	= 7·62	Diameter of shaft	= 6·985

The core is wound longitudinally according to the Hefner von Alteneck principle with 40 convolutions, each consisting of 16 strands of wire 1·753 mm. diameter, the convolutions being placed in two layers of 20 each. The commutator is formed of 40 copper bars, insulated with mica, and the connections to the armature so made that the plane of commutation in the commutator is horizontal, when no current is passing through the armature.

Fig. C, shows a side elevation of the dynamo, Fig. D a cross-section through the centres of the magnets ; Fig. E a section of the core of the armature, in a plane through the axis of the shaft.

The dynamo is intended for a normal output of 105 volts 320 amperes at a speed of 750 revolutions per minute. The resistance of the armature measured between opposite bars of the commutator is 0·009947 ohm, and of the magnet coils 16·93 ohms, both at a temperature of 13·5° centigrade, Lord Rayleigh's determination of the ohm being assumed.

We have now to estimate the lengths and areas required in the synthesis of the characterestic curve.

A_1 ;—from the length of the core of the armature (50·8 cms.) must be deducted 3·4 cms. for the thickness of insulating material between the plates. The resultant area is, on the other hand, as has already been stated, slightly augmented by the presence of the steel shaft. A_1 is taken as 810 sq. cms.

l_1 ; this is assumed to be 13 cms. : *i.e.*, slightly in excess of the shortest distance (12·6) between the pole-pieces.

A_2 ;—the angle subtended by the bored face of the pole-piece at the axis is 129°, the breadth of the pole-piece is 48·3 cms., the diameter of the bore of the field is 27·5 cms., and, as already stated, the diameter of core 25·5 cms., thus, the area of pole-piece is 1,513 sq. cms., and the area of 129° of the cylinder at the mean radius of 13·0 cms. is 1,410 sq. cms. ; this value is taken for A_2 in the curves drawn on diagram

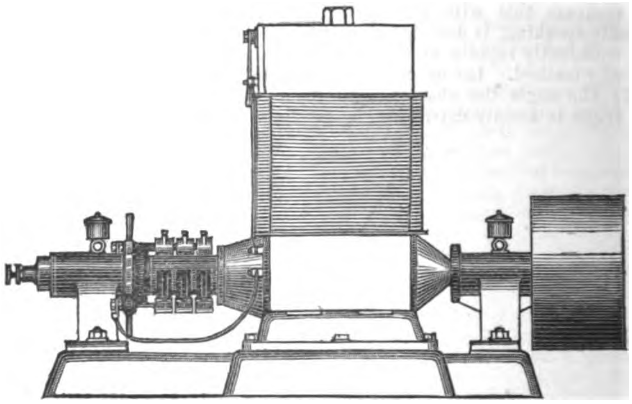

Fig. C.

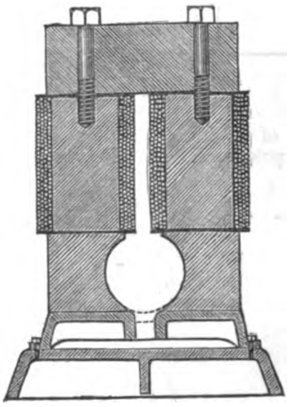

Fig. D.

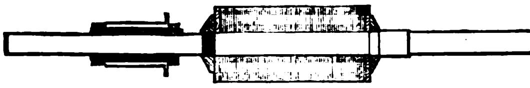

Fig. E.

A. In diagram B, A_2 is taken as 1,600, an allowance of 190 sq. cms. being made for the spreading of the field at the edges of the pole-pieces, or $\frac{190}{160}=1·2$ cm. all round the periphery, that is $\frac{1·2}{1·5}=0·8$ of the distance from iron of pole pieces to iron of core.

l_2 is 1·5 cm.

A_3 is a little uncertain as the forgings are not tooled all over ; it is here taken as 930 sq. cms., but this value may be slightly too high.

l_3 is 91·4 cms.

A_4 is 1,120 sq. cms.

l_4 is 49 cms., being measured along a quadrant from the centre of the magnet, thus :—

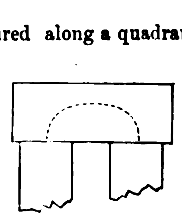

Fig. 3.

A_5 is 1,230 sq. cms., intermediate between the area of magnet and face of pole-piece.

l_5 is 11 cms.

ν was determined by experiment as described below, and its value is taken as 1·32 ; when the magnetising current is more than 5·62 amperes its value should be a little greater.

The function $f(a)$ is taken from Hopkinson, *Phil. Trans.*, Vol. 176 (1885), p. 455 ; the wrought iron there referred to was not procured at the same time as, and its properties may differ to a certain extent from,

Digitized by Google

the wrought iron of these magnets. The curves now explain themselves: the abscissæ in each case represent the line integral of magnetising force in the part of the magnetic circuit referred to, the ordinates the number of lines of induction which also pass through the armature. The results of the actual observations on the machine are indicated, those when the magnetising force is increasing +, when it is decreasing (+). The measurements of the currents in the magnets which were separately excited, and of the potential difference between the brushes, the circuit being open, were made with Sir W. Thomson's graded galvanometers, standardised at the time of use. The irregularities of the observations are probably due to the variations of speed, the engine being not quite perfectly governed. The second construction exhibits quite as close an agreement between observation and calculation as could be expected; the deviation at high magnetising forces is probably due to three causes, increase in the value of ν when the core of the armature is partially saturated, uncertainty as to the area A_3, difference in the quality of the iron. It is interesting to see how clearly theory predicts the difference between the ascending and descending curves of a dynamo. Consideration of the diagram proves that this machine is nearly perfect in its magnetic proportions. The core might be diminished by increasing the hole through it to a small, but very small, extent without detriment. Any reduction of area of magnets would be injurious; they might, indeed, be slightly increased with advantage. An increase in the length of the magnets would be very distinctly detrimental. Again, little advantage results from increasing the magnetising force beyond the point at which the permeability of the iron of the magnets begins to rapidly diminish. For iron of the same quality as that of the machine under consideration a magnetising force of $2 \cdot 6 \times 10^3$ or 28·4 per centimetre is suitable. To get the same induction in other parts of the circuit, the diagram shows that for the air space a magnetising force of 21×10^3 is required, for the pole-pieces $0 \cdot 1 \times 10^3$, for the armature $0 \cdot 2 \times 10^3$, for the yoke $0 \cdot 6 \times 10^3$, making a total force required of $24 \cdot 5 \times 10^3$. Any alteration in the length or the area of any portion of the magnetic circuit entails a corresponding alteration in the magnetising forces required for that portion, at once deducible from the diagram. Similar machines must have the magnetising forces proportional to the linear dimensions, and, consequently, if the electromotive force of the machines is the same, the diameter of the wire of the magnet coils must be proportional to the linear dimensions. If the lengths of the several portions of the magnetic circuit remain the same, but the areas are similarly altered, the section of the wire must be altered in proportion to the alteration in the periphery of the section.

(To be continued.)

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

DISCUSSION ON MR. G. KAPP'S PAPER.

(Continued from page 20.)

Mr. MORDEY inquired whether the magnetic effect of the current in the coils of the armature ought not to be taken into consideration in determining the magnetic resistance of the armature core. The current tended to a certain extent to polarise the core in a reverse direction to that of the field-magnets, hence an apparent reduction of magnetic resistance might be expected to ensue. Thus another reason existed for making the cross section of the field-magnets greater than that of the iron in the core, in addition to that pointed out by Mr. Kapp.

Mr. FRICKER inquired whether the specification of the magnetic induction of a given current in a coil ought not to be expressed in "ampere feet" rather than by "ampere turns."

Mr. CROMPTON said that while it remained a regrettable circumstance that more practical experience was being gained in other countries, yet he felt proud of the fact that it was in England the fundamental work both in theory and in practice had been accomplished—a work which rendered it possible for others to obtain advantages which for the present were denied ourselves. Mr. Crompton then referred to M. Deprez, and with reference to his recent claim to have originated the short, thick, field-magnet, said that he was confident that this claim could not be substantiated. Neither did he think that M. Deprez had in reality been the first to use the "characteristic curve," of which Dr. Hopkinson was undoubtedly the originator. Mr. Crompton thought that the progress which had been made in the construction of dynamos during the last four years could only be considered highly satisfactory, in the light of the fact that during that period the cost of manufacture had been reduced to little more than one-fourth for machines of the same output.

Mr. ALEXANDER SIEMENS pointed out the desirability of not running dynamos up to their maximum capacity. A factor of safety was always taken in other machinery, and a similar rule should be observed in regard to dynamos.

Mr. SWINBURNE said that the principal difficulty in the application of the formulæ, both of Mr. Kapp and of Dr. Hopkinson, arose from the necessity of determining the relative magnetic resistance of the air, which was by no means an easy matter. Mr. Swinburne then pointed out further reasons for believing that Prof. Rowland's formula of magnetic induction was inaccurate. If it had been true it would have been impossible to build a self-exciting shunt-wound machine. Mr. Kapp had said that machines with too little iron could not be compounded. On the contrary, a machine with its field section little more than its armature section is very easy to compound. With regard to laminated field-magnets, it was true that Messrs. Crompton and Co. employed bar iron for their field-magnets, not, however, with the idea of avoiding Foucault currents, which in a properly built machine were negligible in the field, but simply from the facility of construction which the use of bar iron afforded.

Mr. ESSON said it would be useful to have data as to the comparative advantage of armatures having cores composed of discs and of wire, other things being equal. Referring to the necessity for making the cross section of the field-magnets greater than that of the armature cores, he would also like to inquire what should be the exact ratio between these quantities. Great divergence existed among different makers in this respect. In the Mather and Platt machines and in the earlier Phœnix machine the cross-sectional area of armature core is to that of the field-magnets as 2 to 3; in Messrs. Crompton's machines and in Mr. Kapp's the ratio is 1 to 2; in Goolden and Trotter's and some others it is as high as 1 to 1. There must, however, be some point of maximum economy. He had recently made an experiment in which by doubling the quantity of iron in the armature the number of lines passing through it had been increased 90 per cent. Since then he had been reducing the relative section of the field-magnets with advantage. The present practice in the Phœnix machine was to employ the ratio 3 to 4, but he could not say whether they should not still further increase the ratio.

PHYSICAL SOCIETY.—Nov. 13.

Prof. BALFOUR STEWART, President, in the chair.

In opening the proceedings the President referred to the great loss which the society had recently sustained by the death of Prof. Guthrie, F.R.S., the founder of the society and his predecessor in the chair. In the capacity of Demonstrator Prof. Guthrie contributed materially to the success of the society's meetings, and his decease is deeply regretted. The President also announced that the council were considering what steps should be taken to commemorate the late Dr. Guthrie, and that a circular expressing their views would be placed before the members in the course of a few days.

The following papers were then read:—

"*On the Peculiar Sunrise Shadows of Adam's Peak in Ceylon.*" By the Hon. RALPH ABERCROMBY, F.R. Met. Soc. The author prefaced his description by an extract from a paper on the same subject by the Rev. R. Abbay, read before the society on 27th May, 1876, in which the explanation proposed is that the effects are caused by total internal reflection, as in ordinary mirage, the difference of air density being in this case due to the low temperature at high altitudes. The author pointed out that Mr. Abbay neglects the difference of density due to elevation, and that his own thermometric observations disprove conclusively any idea of mirage. The chief phenomena observed were, first, the appearance of a circular rainbow with spectral figures near the top of the shadow of the peak, and, second, a peculiar rising of the bow and shadow, which seem to stand up in front of the observers. Both these effects are traced to the existence of mist clouds in the vicinity of the shadow. Two dark rays or brushes were seen to shoot outwards and upwards from the circumference of the bow, in directions nearly coinciding with the prolongations of the edges of the shadow when seen projected on the lower mist clouds, but the author does not attempt to explain this phenomenon. On one occasion a second and outer bow was seen. The times during which the phenomena were visible were too short to permit sextant observations being taken, but the diameter of the inner bow was estimated at 8 deg. or 12 deg. A totally different kind of shadow is sometimes seen from Adam's Peak just before, and at the moment of, sunrise, which seems to stand up against the distant sky. The author found a similar effect at Pike's Peak, Colorado, which is visible only at sunset. Mr. G. Griffiths remarked that he had often seen similar appearances in Switzerland. In answer to questions by the President and Prof. S. P. Thompson, the author said the reason why the shadows are seen from Adam's Peak at sunrise, and Pike's Peak at sunset, was that the configuration of the land on the west side of the former is similar to that on the east side of the latter, both being low, whereas the opposite sides are high, and therefore unsuitable for showing the phenomena. In all cases he believed the appearances were due to the shadows being projected on clouds of suspended matter in the air at various altitudes. He had not noticed whether the colours were reversed in the second bow seen from Adam's Peak, but observed that this bow nearly but not quite touched the inner one.

"*Note on the Internal Capacity of Thermometers.*" By A. W. CLAYDEN, M.A. Read by Prof. Reinold, secretary. The author proposes to determine the volume v of the mercury by measuring the capacity c of a detached piece of the same tube of known length, and thence inferring the volume of t degrees of the thermometer tube, the length of which is equal to that of the piece of tube taken. By assuming the value of a (the coefficient of apparent expansion of mercury in the particular kind of glass) to be known, the volume of the mercury in the thermometer can be calculated, since $c = t\,a\,v$. Prof. Rücker remarked that there were often considerable differences in the sectional area of different parts of the same tube, and hence the method would probably not be very reliable.

On the motion of the President, a vote of condolence to Mrs. Guthrie on her sad bereavement was passed unanimously.

LEGAL INTELLIGENCE.

The Electric Sun Lamp and Power Co. (Limited) v. Sir Coutts Lindsay and Co. (Limited).

This was an appeal from an order made by the judge in chambers that the defendants should bring into court as a condition to be allowed to defend the action the full sum claimed by the plaintiffs against the defendants, £776. 9s. 8d.

Mr. MOULTON, Q.C., who represented the defendants, explained that the original action was brought against Sir Coutts Lindsay and Co. (Limited), a limited company established for the purpose of supplying electric light installations to the Grosvenor Gallery, Old Bond-street, and neighbourhood, for the full amount contained in five certificates which the plaintiffs alleged were certificates against the defendants for the price of lamps and dynamo machines supplied by the plaintiffs to the defendants. Having read the several documents and the affidavit of the secretary of the plaintiff company, the learned counsel proceeded to argue that this was a case in which the person who swore that affidavit must have consciously kept from the Court most important information with regard to the validity of his claim, and contrived skilfully—he (the learned counsel) would not for a moment say that the secretary had transgressed literally the truth, but had tried to give such a representation as was calculated to deceive the Court. The defence was simply this. The contract was not made with Sir Coutts Lindsay and Co. (Limited), but it was made with Sir Coutts Lindsay personally, and the only connection that the limited company had in the contract was that so far as the dynamos were concerned—the price of which was £475, and in respect of which £237. 10s. was given—was that they agreed with Sir Coutts Lindsay to take them over at the price at which they were supplied by the Company. They had paid £237 already, and they were now perfectly willing to pay into court the other £237, for which they were certainly liable. But they had never had anything to do with the remainder of the contract, which must have been perfectly well known to the plaintiff Company, as the correspondence between the several parties to the action amply testified. He then proceeded to read the letters which had passed between the secretary of the plaintiff company and the defendants, and Sir Coutts Lindsay personally, in support of this contention.

Mr. MANSELL JONES, who appeared for the plaintiffs, maintained, on the other hand, that there was no evidence to show anything in the nature of separate contracts, and that if there was a contract at all, it was indivisible. He submitted that it was an attempt to mix up Sir Coutts Lindsay and Sir Coutts Lindsay and Co. (Limited), to the prejudice of the plaintiffs. What his clients said was that they could not get payment from either one or the other, and that the Company had got the goods at the Grosvenor Gallery, and were carrying on business with these goods, for which they declined to pay the plaintiff company.

On examining the certificates and correspondence bearing on the transactions, the learned judges who heard the case (Mr. Justice A. L. Smith and Mr. Justice Wills) gave judgment in favour of the defendants, deciding that they were liable to pay into court only £237. 10s.

Cook v. The Great Western Railway Company.

On Saturday last, in the High Court of Justice (Chancery Division), before Mr. Justice North, a motion to enforce an injunction, granted in July last, against the Great Western Railway Company, was heard. The plaintiffs were the trustees of the Paddington estate and the tenants of some of the houses near the premises of the Great Western Railway Company, where machinery for the production of electric light, used at the hotel, stations, and premises of that company at and near Paddington, has been in operation for some time past. In July last the Court restrained the company from using the premises comprised in their lease so as to cause a nuisance to the owners or occupiers, or from suffering on any part of the premises works for electric lighting, or other works (except smiths' shops connected with the company's works) which were or might be a nuisance to the trustees, tenants, or occupiers of the Paddington estates, and from maintaining on the premises stationary engines exceeding in the whole 25 horse-power, or which do not consume their own smoke. The operation of the injunction was to be suspended till October 19 last, and the injunction as to the engines was not to be put in operation so long as they did not cause material annoyance.

Mr. H. H. Giffard, Q.C., and Mr. Rashleigh appeared in support of the motion; the Attorney-General (Sir R. Webster, Q.C.), Sir Horace Davey, Q.C., and Mr. R. S. Wright appeared for the company.

Mr. Justice NORTH said that as he understood the argument on the part of the plaintiffs they were absolutely entitled as of right to the immediate issue of a writ of sequestration. He was of opinion that it was a matter for the discretion of the Court whether, though the order for an injunction, as in this case, had not been obeyed, the writ of sequestration should issue or not, or on what terms, if issued or refused, the parties should be put. In his opinion, this was a case in which further time ought to be allowed. The defendants had not in this case contumaciously or wilfully broken the injunction, they had been using their best endeavours to comply with it, and there was evidence that if given two months more they would probably abate the nuisance. He thought it better not to make an order for sequestration and postpone the operation of it, but rather to let the motion stand over till next sittings, which would be in effect giving two months to the defendants. If at the expiration of that time he found the injunction was not complied with, it would take a great deal to induce him not to order the writ to issue.

Notice of appeal was at once lodged against the decision of Mr. Justice North, and the case was again heard yesterday in the Court of Appeal, before Lords Justices Cotton and Fry, the same counsel appearing as before.

The ATTORNEY-GENERAL and Sir HORACE DAVEY exhaustively criticised the evidence that had been given in the affidavits at the trial in July last, to show that the nuisance complained of was much exaggerated. They also contended, as the learned judge pointad out, that the defendants had not been guilty of a wilful violation of the injunction, but on the contrary had used every human means in their power to comply with it, and that probably by the time the two months had passed they would be able to satisfy the inhabitants on the score of the nuisance complained of.

Mr. GIFFARD replied to the arguments brought forward by his learned friends at great length, and pointed out that none of the evidence—even including that of so eminent an authority as Sir Frederick Bramwell—afforded the smallest hope that some means would be found to abate the nuisance within the time. The experiments of the last twelve months had been a long series of failures. It was a hopeless task. If there were three dynamos driven with 600 horse-power engines just behind their lordships, could the evidence, even of an expert witness, that possibly in two months' time some means might be devised for abating the annoyance from those engines after the futile attempts that had been made to do so, have the smallest weight. He ventured to say that if their lordships' sanctuary had been invaded in that way they would not give the two months asked for by the defendants. He submitted that the defendants had been guilty of wilful disobedience, although not in the sense of malicious disobedience to the order of the Court. He thought that to imply that the evidence which had been forthcoming from so many independent sources was exaggerated in the absence of cross-examination was a suggestion which their lordships would not listen to. Let their lordships consider the consequence of refusing the plaintiffs the injunction they asked. It would mean that they would have to continue under an infliction which no subject of this realm, but least of all a subject who had been protected by an order of the Court, ought to be compelled to endure.

The Court then rose, judgment being deferred until this (Friday) morning.

COMPANIES' MEETINGS.

West Indian and Panama Telegraph Company (Limited).

The nineteenth ordinary general meeting of the members of this Company was held at Winchester House, 50, Old Broad-street, on the 17th inst., under the presidency of C. W. Earle, Esq.

The SECRETARY (Mr. R. T. Brown) read the notice convening the meeting, and the minutes of the last meeting, which were approved by the present meeting, and signed as correct by the Chairman. The report of the Directors was taken as read.

The CHAIRMAN: On the last occasion when we met to discuss our affairs I introduced the question of the report by the remark that we were suffering under the depressing influence of declining traffics. That depressing influence has not passed away, and anybody who watches the sugar market will see very good reason why it does not pass away, and would be very much surprised if it did. Sugar which in the first years of this decade averaged about 20s. to 21s. per cwt. is now selling at something under 11s. per cwt., and when we last met the average price was about 13s. Sugar, therefore, has declined from what we may call the normal price of the brand of sugar—Muscavado—very nearly 50 per cent. since the days when we were rather more prosperous than we are now. Not only have the West Indian Colonies suffered that great fall in the price of their principal product, but some of them were visited during the last summer by convulsions of nature which have had very disastrous effects upon them. Jamaica has been twice swept by a hurricane, and a great deal of destruction has occurred there, and St. Vincent was visited by a tornado on the 16th of August last, which, in the words of the Governor in his late address to the Legislative Council, it would be impossible for anyone to forget who had witnessed its devastating effects. This disaster at St. Vincent, coming upon a long period of depression in the sugar trade, has forced them to reconsider their expenditure—their Budget—and I am sorry we received a telegram the day before yesterday, announcing that one of the reductions they had made was in our subsidy, reducing it (temporarily I hope, though the telegram does not say so) from £800 to £400 a year. Until we get the documents, detailing the communication from the colony (this is merely a telegraphic message sent by our own people) we shall not know how to deal with it; but it is to be feared that absolute necessity has made them reduce it. Whether they have reduced us in equitable proportion with their own charges remains to be seen when the details come more fully to our notice. The account that we tender you today as the effect of the reduction of the traffic which is announced in our report offers no subject for remark. I shall be very happy to answer any question that may be put, but the expenditure side of the account is almost identically the same as it usually is as far as it is controlled by us. There is a saving of about £1,400 compared with the corresponding period; but that saving arises entirely from items in Abstract C which refers to the repair and renewal of the cables, and which is always a varying item, and one which it is impossible for us to control. It depends so entirely upon the work which the ships have to do, the luck they have in doing it, and the losses in their grappling ropes, and a variety of other causes which make that Abstract C a very varying item. As to our cable repairs, the principal cable operations we have had to deal with in the half year are referred to in the report. You may remember last half year that the original line

Digitized by Google

between Jamaica and Porto Rico, which we had repaired, became inoperative, and we decided then to grapple for it to get it where we could upon each side of the break, and lay in a new piece of cable of considerable length, but in shallower water, the water being so deep where the original cable was laid that it was impossible to recover it. Therefore we had to lay in a considerable portion of new line. While that operation was being conducted we had a break in the Colon cable, and the ship being in communication with Porto Rico we immediately instructed it to go to the repair of that cable, which was then rather important as earning money. She repaired one break and found there was another, and she has now been some time on that operation. She has recovered the Colon end and has spoken to Colon, but since then we have heard nothing more. It is satisfactory to find that she lifted that cable in considerable depths, and it appears, as far as we have heard, to be in good, strong condition, though it has been down about 15 years (hear, hear). I may mention (perhaps I ought to have mentioned this while talking about the account) that the debenture debt of £50,000 falls due on the 31st Dec. next, and we intend to propose to the holders of these debentures to extend the time upon an interest of 5 per cent. If there are any holders of debentures who prefer not taking 5 per cent. we shall be able to transfer them [hear, hear]. We shall arrange for it. The security of the Company has so much improved owing to our reserve fund and the accumulation we have made that we think it will be a very good investment at 5 per cent. I shall renew mine, and if any debenture holders are here they will perhaps communicate with the secretary if their names are not known to him already. There is one point in our report which is an element of considerable satisfaction—that is, the abandonment of the proposed Bermuda-Jamaica cable. That would have been, I am afraid, a very injurious cable for us. It would have brought competition into the midst of our system, competing under a Government guarantee, and it is highly satisfactory to have the information from the Secretary of State that the idea, for the present, at all events, is abandoned. I hope, seeing that Jamaica is connected by three cables with the rest of the world, and that a strategical cable of that sort—for it is purely strategical, and in case of a great war, when it would only be of any importance, it would be sure to be cut—I hope that the Government will save their money and ours by not going into the business at all. I think I have touched upon all the points that occur to me to refer to. I shall be very happy to answer any questions. The outlook in the West Indies is not at this moment encouraging, but we must hope when things change (as for instance by a change of products—for if sugar is to depart they may find some other means for cultivating their very fertile soil) that there will be some return of prosperity both for them and us. I now beg to propose that the Directors' report and accounts to the 30th June, 1886, submitted to this meeting be and the same are hereby received and adopted, and that, as recommended by the Board, a payment of 8s. per share on account of arrears of dividend on the first preference shares be and the same is hereby declared.

Mr. W. FORD seconded the motion.

Mr. W. GRIFFITH said he thought the report was one that must commend itself to the Company at large, and the statement they had listened to from the Chairman also, he thought, corroborated the hope which the report was calculated to excite. It was something to be informed that their security was so good that they might expect now to change a 6 per cent. debenture debt into one bearing 5 per cent., and considering that all parts of the world had been suffering from a depression of trade they must say it was satisfactory that they had so far kept up their business. He had been struck with certain expenses appearing in Abstract C. The Cuba Company, whenever they had any cable laid down, made terms with the manufacturer to keep it in repair for a certain number of years. That arrangement saved the Directors a great deal of anxiety, and enabled them also to withhold a portion of the capital which was paid to the manufacturers year by year instead of in one large sum. He admitted there might be some difficulty in applying such a principle to the case of this Company, which had so many stations, but he suggested it for the consideration of the Directors.

Mr. MORTEN said that the total receipts for the Christmas half year were £38,000, and for the June half year £45,400. The interest on their investments and so on had returned them £4,100 for the year, so that their total income for the last year was £87,500, the total expenditure for the year having been £49,600. Deducting that from the total they had a net profit of £38,000. The current interest on the first preference shares was £20,700, and on the second preference shares £2,800, making a total interest of £23,500. He had included in the expenses the debenture interest. They were thus left with a total balance after paying preference shares interest of £14,500. That would give 3s. a share to the ordinary shares. The reserve fund was £122,800, plus the improved value of the securities of £5,300. There was nearly a profit of £6,000 on the investments forming the reserve fund, which must be taken to amount to at least £129,000. Further, they were replacing their cables not out of the reserve fund, but out of the current earnings. The Company was on a splendid commercial footing. He held that they could easily raise £100,000 by debentures at 4½ per cent., and they could then pay off the existing debenture debt and the arrears of dividend on the preference shares, and start afresh, paying a dividend on the ordinary shares, and going on building up the reserve fund. They must either be in a very poor position, in which case they ought not to pay £2,100 a year for Directors' fees, or else they were in a very good position, in which case the shareholders ought to be sharing in the benefits.

Mr. GUESDON said, with regard to the remarks which they had just heard, the course which the Company had adopted might not be agreeable to the ordinary shareholders. He himself held the three classes of securities; and, therefore, he thought he was able to give an unbiassed opinion. The Directors, in his opinion, had acted wisely in forming the reserve fund. Mr. Griffith had spoken about a guarantee which had been given to another company by the company that made its cables. *Apropos* of that matter, he was very pleased to see the name of another company mentioned in the Directors' report, and they had entered into a contract with Henley's Telegraph Works Company for the manufacture of the cable. He thought, but he did not say it was so in this Company, that the industry of manufacturing cables had been very much stifled, as that was one of the powers which could be exercised by the great companies. As to the value of the ships, he did not know whether they insured for the whole cost of the ships or whether they insured against total loss. He advised them to insure against total loss, when the matter would be made more clear, and they would be paying a smaller premium.

The CHAIRMAN said that their idea in regard to the insurance of the ships was that they should have the money for the ship in the event of its loss.

Sir JAMES ANDERSON pointed out that the Company did not possess enough yet to replace the ships.

Mr. GUESDON referred to the issue of proxies, and regretted that the Directors had persisted in issuing them in face of the injunction. If they were to be issued, they ought to be issued in blank form.

The CHAIRMAN pointed out that it was not in connection with *bonâ fide* shareholders that the Directors issued proxies, but against "bears" and wreckers, who might come to their meetings, and injure the Company, unless they took the precaution of sending out proxies, which, however, on the present occasion had been sent at the expense of the Directors.

Mr. GUESDON wished to know what services Mr. Cyrus Field rendered to the Company that he should be one of the Directors.

The CHAIRMAN said that they were bound by the original agreement to have Mr. Field on the Board, and that that gentleman rendered them valuable assistance. The Company had constant relations with American companies through whose lines they worked, and there were frequent subjects to which Mr. Field attended on the other side.

Mr. GUESDON said that he noticed in the case of another Company a very satisfactory feature, namely, that the Directors, owing to the great depression that existed, had reduced their fees, and it seemed to him that as this Company had a considerable falling off in revenue, the Directors might follow that example. If the Directors attended a meeting once a week that meeting cost the Company £40.

The CHAIRMAN replied that the Directors' attendance at meetings was only one item in connection with their work.

Mr. GUESDON said he would not move any resolution on the subject, but it would be acceptable if the Directors consented to reduce the amount they took for their fees. He had no hesitation in expressing his confidence in the Board.

Mr. JOHN NEWTON said he was very pleased to see that the policy of the Directors was freely criticised. As to the reserve fund, he could not conceive how anyone could ignore a part of his property, and say that the interest from that property was not his income. The money they derived from the investment of their reserve fund ought to go to the credit of their annual revenue, and when they wished to add anything to the reserve fund let the total sum be shown. He thought the Directors were perfectly right in issuing proxies at their own expense, but it would be altogether *ultra vires* for them to issue proxies now at the expense of the Company. It was perfectly legitimate for shareholders to move resolutions at a meeting, as he himself had done, in order to get an expression of opinion, but it was not right for any shareholder to have the power of upsetting the Company.

Mr. WM. ABBOTT thought it exceedingly gratifying that the Company occupied the strong position it did, and the Directors were to be commended for the manner in which they had conducted its affairs to such a successful result. The Chairman had used the word "wrecker," and he (the speaker) could speak with some experience on that point, as he had wrecked the Company himself.

The CHAIRMAN: You did not wreck the Company.

Mr. ABBOTT said he succeeded in wrecking the late Board, and the present Board was the result of the chaos which at that time he created. It was only right, therefore, that he should be present at the meeting to express his satisfaction at the position which the Company now occupied, owing to the exertions of Directors for whose appointment he was in a great measure responsible. He agreed with one speaker that the property of the Company in the market was in a lamentable position. It was lamentable that the whole £883,000 of ordinary share capital was now selling at something less than £80,000, but when they considered the financial strength of the Company, he thought it was something to have attained. A gentleman had called attention to the paltry matter of Directors' fees, but it should be remembered that by their judicious selection of investments for the reserve fund, the Company had benefited by some £6,000 a year. He spoke of the great services which they had rendered to the West Indian Colonies, and thought the sacrifice they made was far more than the subsidies they received were worth.

Mr. MULLENS said he considered that only a portion of the debentures ought to be extended at 5 per cent., and that the other portion should be paid off out of the reserve fund. They were paying 5 per cent. for their debentures, and on their investments they only got 3½ per cent.

The CHAIRMAN, in reply, said with regard to Mr. Griffith's remark about the arrangement made by the Cuba Company, the position was quite exceptional. He very much doubted if they could get any contractor to take the risk of keeping in repair a cable on the other side of the world, and if they could he would make such a charge that it would be outside the power of the Company to bear. The present Board had laid no contractors' cable. They had bought their own cable, and sent it out by their own, or by a hired ship, thus getting rid of all contracts, and doing things very much more cheaply than his experience told him that manu-

Digitized by Google

facturing companies would charge. Mr. Guesdon made some remarks about separating the items of messages and subsidies. He thought there would be disadvantages in that. As to the insurance of their ships they had always gone on the principle that if they lost a ship they ought to be able to recover the money that would replace it. In connection with this matter they had acted on a suggestion made by Mr. Guesdon at a former meeting. They had reduced the value of their ships, but they would look into the question again. Mr. Newton had made some remark as to dealing with their investments. He confessed that he did not see that there was much difference in the system. Mr. J. G. Griffiths advised them on that matter, and the Directors framed their accounts on that gentleman's guidance and suggestion as to the details and the technical part. It seemed to him that it was pretty clearly stated what the interest was that was carried to the general year's interest on the investments, and the sum they added as well.

Mr. NEWTON said that the shareholders ought to see one lump sum carried to the reserve fund, and that then each half-year they should see the exact sum added to it. A sum of money should not be credited to a reserve fund on the reserve account as interest on the investment, but the total amount added to the reserve should be clearly stated in the profit and loss account.

The CHAIRMAN said that the point raised was one upon which "doctors differed."

Mr. J. G. GRIFFITHS (the auditor) said that the reserve fund was in fact an insurance fund, and as all funds should be dealt with the revenue from that fund should go to the insurance. It belonged to it, and had nothing to do with the ordinary income of the Company.

Mr. WEAVER said that if they put the interest to the general revenue and divided it they would only have to put more to the reserve fund.

The CHAIRMAN said that with regard to the suggestion of paying off part of the debentures, that went to the whole question as to whether the reserve fund was in excess of what it ought to be. If they said that they would only renew half the debenture debt and pay off the other half, they would reduce the reserve fund by £25,000, and, according to their calculations, they would have to build up the reserve fund again more rapidly.

Mr. GUESDON said that sooner than see the reserve fund interfered with he would advocate the adoption of a bold course, and urge them not to insure their ships. If they ran them successfully for a few years they would be greatly benefited.

Sir JAMES ANDERSON: Suppose you did not? Suppose you ran into another ship?

Mr. GUESDON said that the running down clauses were only £8 a ton.

The CHAIRMAN put the motion, which he declared carried, with one dissentient.

Mr. MORTEN then proposed the following resolution: "That it be recommended to the Board that, inasmuch as this Company is possessed of investments of the value of about £117,000, returning under 4 per cent. interest, the present debentures of £50,000 be not extended at 5 per cent., and that the Directors be earnestly requested to take steps to pay off the arrears of preference interest, and start the Company on a better commercial basis."

A SHAREHOLDER seconded the motion.

Mr. GUESDON moved as an amendment "That all matters relating to the extension of debentures and arrears of interest be left in the hands of the Board."

Mr. WILLIAM ABBOTT seconded the amendment.

The CHAIRMAN put it, and declared that only two had voted against it. He therefore declared the amendment carried, and intimated that that closed the business.

Mr. ABBOTT proposed a vote of thanks to the Chairman and Directors for the way in which they had administered the Company's affairs during the half year. He could not, he said, keep his eyes off the reserve fund, which he thought the Company was very fortunate in possessing.

Mr. PARSEY seconded the motion, and

The CHAIRMAN having acknowledged the compliment, the proceedings terminated.

The Pilsen Joel and General Electric Light Company (Limited).

An extraordinary general meeting of this Company was held on Wednesday at the Cannon-street Hotel, Sir Rawson Rawson in the chair.

Mr. W. H. TRENTHAM (the Secretary) having read the notice convening the meeting,

The CHAIRMAN said: I do not know that it is necessary for me to do more than repeat what I said before, that the object of this meeting is to reduce our capital, to wipe off what we have lost and what there is no immediate hope of recovering, but which will not prevent us from making as large a dividend in future as if this dead weight remained on the books against us. It will enable us as we make profits to declare a dividend to our shareholders. It was passed unanimously, after some discussion, at the last meeting, and I hope it will meet with your favour on the present occasion. I beg to propose: "That if an order of the Court be obtained for confirming this resolution the capital of the Company be reduced by cancelling the sum of £1 per share on the 28,000 shares of the Company of £3 each with £2. 5s. each called up thereon, and the sum of £1. 15s. per share on the 100 fully paid-up shares of £4 each, as being capital which has been lost, or is unrepresented by available assets, and that the Memorandum of Association of the Company be modified so as to carry into effect this resolution."

Mr. WHATELY seconded the resolution, which was carried unanimously.

The CHAIRMAN: I hope as soon as we can get the Court to move in the matter, we shall call a general meeting and lay our year's account before you, which I trust will meet with your approval.

The proceedings then terminated.

THE EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY, LIMITED.

NOTICE IS HEREBY GIVEN that in conformity with the conditions contained in the Debentures of the above Company, the following FIVE PER CENT. MORTGAGE DEBENTURES for payment at par, on the 1st January, 1887, at the Banking House of Messrs. Barclay, Bevan and Co., 54, Lombard-street, E.C., when the Interest thereon will cease, were this day drawn at the Offices of the said Company, at Winchester House, No. 50, Old Broad-street, in the City of London, in the presence of Sir James Anderson, one of the Directors, George Draper, Esq., Secretary of the said Company, and the undersigned Notary Public.

NUMBERS OF DEBENTURES DRAWN THIS DAY.

NOTES.

TELEGRAPH CABLE REPAIRED.—The cable between San Juan del Sur and Panama is repaired.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended the 19th inst. amounted to £5,246.

THURSDAY ISLAND CABLE.—We are informed that this cable has been successfully laid by the Eastern Extension Company for the Queensland Government.

ESTIMATES REQUIRED.—We would call the attention of electric light contractors to an advertisement, which appears in another column, asking for estimates for lighting a number of offices in the City.

FOULING A CABLE.—The United States schooner "Grampus," while attempting to weigh anchor, recently fouled one of the Atlantic cables near Jeffrey's Ledge, and was obliged to cut her hawser. No damage was done to the cable.

LIGHTING OF THE RIVER PLATE BANK.—It has been decided to introduce the electric light into this bank, and the work has been put into the hands of Messrs. Drake and Gorham, of 2, Prince's Mansions, Victoria-street, S.W.

SPANISH TENDERS.—Tenders are invited for the 15th of December for the supply of 20,000 insulators for the service of the State Telegraphs. The conditions are on view at the offices of the General Board of Posts and Telegraphs, Madrid.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended Nov. 19 were £4,290, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

"LIVES OF THE ELECTRICIANS."—Messrs. Bell and Son, of Covent Garden, are about to publish a series of volumes under the above title. The first number—which is to be ready next week—is written by Mr. W. T. Jeans, and contains biographies of Prof. Tyndall and Messrs. Wheatstone and Morse.

TENDERS WANTED.—The North-Eastern Railway Company are inviting tenders for the supply of telegraph apparatus, wire and line stores. Forms of tender may be obtained on application to Mr. Graves, Telegraph Department, York, and must be returned by December 1st to Mr. C. N. Wilkinson, secretary, York.

SOUTH WALES UNIVERSITY COLLEGE.—We have received a copy of the calendar of the University College of South Wales. The Physical Section of this college is under the direction of the Principal, Prof. Viriamu Jones, M.A., B.Sc., assisted by Mr. W. P. Hensley, B.A. A course of electrical engineering is provided, and the laboratory contains a gas engine and dynamo machines.

THE ATTEMPTED BETTING FRAUD.—The case of Myer Myers, who was charged with attempting to corrupt the servants of the Exchange Telegraph Company, for the purpose of fraudulent betting, will not be proceeded with, his counsel (Mr. Kisch) having announced in court on Tuesday that the accused had inadvertently taken an overdose of laudanum, and died on the preceding Thursday.

APPEAL CASE.—Gilman *v.* the Gülcher Electric Light and Power Company.—This appeal, on the part of the plaintiff, from the judgment of Mr. Justice Grantham, who disallowed his claims for fees as director of the defendant company, in respect of the period from 31st December, 1884, to the 14th May, 1885, is to be heard to-day (Friday), before the Master of the Rolls, Lord Justice Lindley, and Lord Justice Lopes.

THE BARTHOLDI STATUE.—The present arrangements for lighting the statue of Liberty are generally acknowledged to be a failure, and Mr. Goff, the President of the American Electric Manufacturing Company, by whom the installation was supplied, has therefore offered to light the statue at his own expense for the present on condition of being permitted to experiment as he pleases as to the best disposition of the lights.

EXHIBITION AWARDS.—Messrs. Marshall, Sons and Co. the well-known engineers, of Gainsborough, were awarded a gold medal at the recent International Exhibition at Liverpool, where they supplied the whole of the motive power for the electric lighting. The same firm obtained a grand diploma of honour at the Edinburgh Exhibition, and have also been awarded prizes at Czernowitz, Austria, and at Gorinchem, Holland.

AUSTRALIA.—A conference is being held at Melbourne between the Postmasters-General of several of the Australian Colonies, and among other questions the delegates are expected to take up is that relating to cable communication and cheap rates. The question is a large one, but is becoming of the utmost importance. It involves the consideration of a general system of guarantees, with the tariff rates controlled by the guarantors.

THE AMERICAN TELEPHONIC LITIGATION.—"It seems probable," says the New York *Electrical Review*, "that the great telephone litigation of the past several years will be concluded during 1887. The Supreme Court of the United States on Monday granted a motion made last week to advance and hear together the telephone cases—six in number—now entered, and ordered that they be set for argument as one case on January 24th, at the head of the calendar."

PERSONAL.—Dr. R. Mullineux Walmsley, senior demonstrator at the Finsbury Technical College in the department of Applied Physics and Electrical Engineering, has been appointed Principal of the Sind State-Aided Technical College, which is now being established at Kurrachee. Dr. Walmsley's numerous friends, while congratulating him on his appointment to so interesting and important a post, will feel much regret that it involves his leaving this country.

SUICIDE BY TELEPHONE.—According to the *Figaro*, a young lady committed suicide at Brussels the other day, under very extraordinary circumstances. Having heard of the unfaithfulness of her lover, she called him up at his place of business by telephone, and asked him if it was true that he was going to marry Mdlle. ——— ? He replied that it was quite true. "Then good bye, for ever," were the next words that reached his ears, followed by the report of a pistol. The poor girl had shot herself.

PRINTING BY ELECTRICITY.—The *American Inventor* of Cincinnati, a large monthly journal, says:—"We print this month's issue for the first time by means of electricity. This is the first plant of the kind in this State. We are running four presses with a single Sprague motor, and find it an immense advance on any other kind of power. The expense for repairs to the motor cannot amount to 10 per cent. of that required for either steam, gas, or water hot air engines, and we see no reason why it will not give for many years to come as good results as at present."

ELECTRIC LIGHT AND VEGETATION.—In the neighbourhood of the tower lights, with which so many of the American cities are now illuminated, the influence of the arc light upon vegetation is becoming very noticeable. A gentleman in Davenport, Iowa, whose garden is within 100ft. of an electric light tower, says that his lilies, which ordinarily close their

Digitized by Google

petals long before sunset, now again unfold a few minutes after the lamps commence to burn. It is also observed that the foliage of the trees in Detroit was more luxuriant this summer where the light has fallen on them.

Electric Light in Mines.—At the meeting of the South Wales Institute of Engineers, Cardiff, on Tuesday last, Mr. Hann, one of the managers of the Powell-Duffryn Collieries, described the method patented by him for lighting miners' lamps by means of electricity so as to avoid there ever being a naked light in the mines. The current is supplied by accumulators "of such low power that they may be placed anywhere in the mine with safety." Mr. Mordey also read a paper on the electric lighting of mines, one of the features of his scheme being to surround incandescent lamps with water.

The Fire at Hampton Court Palace.—After the calamitous fire in this palace in 1882, H.M. Office of Works decided to have all the residential apartments in the palace provided with electric appliances, and Mr. Zimdars, of Hatton Garden, was instructed to provide and fix his electric bell system with duplicate indicators and about 80 separate night-alarm bell pushes communicating with the fire brigade engineer's residence, and also with the office of the clerk of the works. The disastrous outbreak which has just occurred would very probably have proved even more calamitous had not these precautions been taken.

A Costly Installation.—The Hotel de Ville at Vienna possesses an installation of 564 16 candle-power lamps, and a few of 30 candle-power. According to some figures given at the recent meeting of the gas engineers of Austro-Hungary the first cost of this installation amounted to very nearly £6,000, while the cost of working, including interest and depreciation at 10 per cent., exceeded £1,300 per annum. The number of lamp-hours is not ascertainable, but it appears that the total number of hours of working is only about 170 per annum, while on many evenings only 20 or 30 lamps are actually in use. The dynamos employed were built by M. Egger, who also has charge of the installation.

Village Lighting in Holland.—The small village of Kinderjik, in Holland, possesses a central lighting station of a somewhat remarkable character. The place was once lit by gas, but owing to the extreme dampness of the soil the pipes rusted away with such rapidity that the works were actually abandoned from this cause. The engine house stands upon piles, and is surrounded by water. A 400 light Edison plant has been put in, and is running with perfect satisfaction. The service is remarkably cheap, varying from about 10s. 6d. per annum for one 16 candle-power lamp to about 9s. each per annum for 20 lamps; the lighting ceases at 12 p.m. It is found that the lamps are taken by villagers, whose earnings do not amount to more than 4s. per day. The capital invested is said to be only about £600, and the company are not allowed to pay more than 5 per cent. per annum. With regard to the rusting of iron, it may be mentioned that the same difficulties have been experienced by the gas companies in the neighbourhood of the salt lakes upon the plains of Mexico.

Junior Engineering Society.—At the last meeting of this society a paper was read by F. Harman Lewis, Stud. Inst. C.E., on "The Electrical Government of the Steam Engine." The author having indicated the particular necessities for, and requirements of, steam engine governors, proceeded to show as an illustration of the importance of perfect regulation how great was the demand for accurate and sensitive regulation of speed in dynamos, and pointed out the various respects in which the centrifugal governor had failed to comply with this demand. Electrical devices for governing the speed of dynamo machinery motors were then considered, and Jamieson's, Richardson's, and Willans' electrical governors were described, the author claiming for the latter certain advantages which the others did not possess, the most noticeable being its great freedom from friction. From certain tests of the efficiency of this governor it appeared that, although the current ranged from 230 to 500 amperes and the boiler pressure from 85lb. to 105lb. per square inch, the electromotive force varied only ·5 volt, these figures being obtained from readings taken at the installation at Victoria Station. The paper was illustrated by some excellent wall diagrams, and a specimen of the Willans electrical governor, kindly lent by its inventor.

Central Lighting Station for Sheffield.—From the *Sheffield Daily Telegraph*, of 20th November, we take the following:—"An electric light supply station, on a large scale, has just been completed by Messrs. Tasker, Sons, and Co., electrical engineers, with the object of supplying light to public buildings, hotels, shops, works, &c., in any part of Sheffield. It is clear, from an inspection of the station, which is enclosed within substantial buildings, in Commercial-street, that preparations have been made for considerable future development and demand for this system of lighting. First, there has been fixed a compound condensing engine of 200 indicated horse-power. Supplying this engine with steam is a large Galloway boiler, fitted with Proctor's mechanical stoker and other improvements. The fly-wheel of the engine works on to counter shafting, and from this the power for the dynamo is taken. At present in the dynamo room are fixed a Thomson-Houston 45-light machine and one Siemens shunt-wound machine, which latter will be employed to charge secondary batteries for incandescent lighting. It is proposed to rent out lights to consumers for an annual sum per lamp, which will include maintenance and attention, thus relieving customers from all trouble in this respect, and already a very encouraging start has been made in the supply of lights to various consumers."

National Telephone Company's Conversazione.—The annual *conversazione* of the *employés* of the National Telephone Company took place on Saturday in the St. Andrew's Hall, Glasgow, a numerous company being present. During the evening the chairman of the company, Colonel R. Rainsford Jackson, delivered an interesting address on the progress the telephone was making in the public estimation. Five and a-half years ago, he said, there were only 317 subscribers in the Glasgow district, whereas they now had no fewer than 1,857, while the company at present had 137 offices, as against 33 five and a-half years ago. At that period, too, the total number of messages sent in a year was 688,000, while it had now reached the high total of 5,020,000. He might add that he considered the telephone service in Glasgow was as perfect as it could be. Sir Wm. Thomson also spoke, and referred to the incredulity with which the announcement of the invention of the telephone had been received, and gave an instructive little sketch of the first experiments made with the instrument. At one of these meetings of scientists in America, at which he had the privilege of b ing present, the first message sent over the wires was, "To be or not to be—that is the question" [laughter.] No doubt they would agree with him that the question had been sufficiently answered. He wished to give his testimony to the efficiency of the Glasgow staff.

The Electric Light at Ingestre Church.—A special service was held in Ingestre Church on Saturday night to celebrate the lighting of the church by electricity, a work which has been carried out entirely at the cost of Lord Shrewsbury. The chancel had been tastefully decorated with flowers

Digitized by Google

and plants, and there was a large congregation, which included many of the clergy from the neighbouring parishes. The church, one of Sir Christopher Wren's works, although comparatively small, contains some specially good examples of carved oak; and the rood screen, pulpit, and reading-desk are worthy of special attention. It is situated immediately adjacent to the residence of Lord Shrewsbury, and the current for the electric light is derived from the same plant which supplies the mansion. This plant is capable of supplying some 500 lights. All the machinery is in duplicate, so as to act as a provision for special occasions, and to guard against breakdown, but it is worthy of notice that although the light has now been installed at the hall for about twelve months, and used in some parts day and night, on no occasion whatever has it failed, or been necessary to resort to the duplicate machinery. The illumination of the church is carried out by means of incandescent lamps, of which there are some twenty-five attached to specially designed hammered iron standards, and is carefully diffused by ruby glasses. The pulpit light is so arranged that the light is concentrated chiefly upon the book without being seen. The whole of the electrical work at the hall, stables, and church, and surrounding buildings, has been carried out and designed by Mr. Taylor-Smith, of 101, London-wall, London, E.C.

The Proposed Paris-Brussels Telephone Line.—We gather from the *Bulletin International de l'Electricite* that the negotiations which have been for some time in progress for the establishment of an international telephone line between Paris and Brussels have been brought to a satisfactory issue on all points save one. It appears that the French Government are prepared to construct a special metallic circuit line of silicum bronze wire from Paris to the frontier, and very naturally wish the Belgians to complete the line to Brussels on the same plan. The Belgian Government, however, entertains a decided preference for the Van Rysselberghe system, and as their contribution they offer to equip an existing telegraph wire with the Van Rysselberghe apparatus. The Belgians may be pardoned for entertaining a fondness for the methods introduced by their countryman; but there can, we think, be little doubt that they will be pushing the system beyond its proper sphere if they insist upon its employment in this particular case. We have always regarded the Van Rysselberghe system as an ingenious device whereby a wire not overburdened with telegraph work may in some cases advantageously be made to do double duty; but it is well known that the system is not applicable to telegraph lines worked at a high speed of transmission, nor is it conducive to the most satisfactory telephonic communication. According to our contemporary, the system has not met with any great success in France, the experience gained upon the Paris-Rheims line is spoken of in particular as by no means encouraging. Nevertheless we shall hope that the Belgian Government will consent to build a special metallic circuit line from Brussels to the French frontier, and in that case we have little fear for the success of the scheme.

Electricity in the West of England.—The *Western Morning News* writes as follows:—"It is cheering to see the spirit displayed by some of the more important towns in Cornwall in arranging for experiments with electric lighting, and Tavistock also shares the honour. But what about Plymouth and Devonport? Surely it is time that the metropolis of the West made some movement in the matter. The reason for their lethargy cannot be that the gas is so good and so plentiful, for there are few large towns in England the streets of which are worse lighted. As for the public buildings, it is painful to observe the 'dim, religious light' which is made in some of them to do duty for real illumination. There is scarcely a public building or church or chapel which is well lighted, and where even enough gas is burnt to make it easy to read, the heat throughout the greater portion of the year becomes so intolerable that the gas has to be turned down during a part of the evening, and that gives rise to a flickering which is most painful to the nerves and injurious to the eyes. Surely if in some central spot of Plymouth a powerful steam engine and an adequate dynamo were erected, it would be easy to supply a group of buildings, say the Guildhall, St. Andrew's Hall, George-street Chapel, Royal Hotel, the Theatre, and Athenæum, all within a compass of 500 yards; and the electric light would be a great attraction, as well as minister to the comfort and health of those who frequent the buildings. Some of the spirited tradesmen also would do well to give the matter their attention. It is true that shopping after dark has become unpopular, and desirably so; but for some months in the year it becomes dark in the shops and warehouses long before a reasonable hour for closing, and not only does the electric light supply a good light by which to judge of colours, which cannot be properly seen by the aid of gas, but the health of the *employés*, not to add the customers, is worthy of consideration. A co-operative experiment, to last a few months, would give the matter a fair trial, and even if the electric light be found to cost more than gas, it would be a luxury well worth some outlay."

Proposed Atlantic Cables.—The following letter appears in *The Times* of November 23rd:—"26, Old Broad-street, London, E.C., November 22nd. Sir: If you will kindly refer to the prospectus of the International Cable Company (Limited), which appeared in your columns to day, you will find the following paragraph, which, being printed in red letters, is evidently relied upon by the promoters, and is expected to act as an inducement to the public to subscribe their money to the new enterprise:—'The directors regard with interest the sudden change of policy by the Associated Companies, and the war of rates now ruling. Assuming this company obtains a fair share of the traffic, the lower capital, after allowing for working expenses, repairs, and renewal fund, would enable them even at 6d. to pay a satisfactory dividend.' For the information of possible investors, the following figures will be useful:—The total Atlantic cable traffic at the 6d. per word tariff yields £300,000 per annum. Presuming that the new company intend to lay two cables, their proportion would be 20 per cent., £60,000 per annum. If only one cable be laid, then their proportion would only be £30,000 per annum, which, irrespective altogether of the question of the capital cost of the new cables, would only be sufficient to pay working expenses and repairs, leaving nothing either for renewal fund or dividend. The conditions under which the Direct United States Cable Company succeeded in getting for a short time 37 per cent. of the whole traffic are entirely altered now. Then there were only four cables across the Atlantic, now there are ten. The tariff at that time was 3s. per word, and the traffic in consequence limited; now the tariff is 6d. per word and the volume of traffic enormous, so that the new company could not carry more than their proportion expeditiously. I have only dealt with that part of the scheme which, at an estimated cost of £830,000, is to connect Europe with Canada and the United States of America, because, as the bulk of the traffic at 6d. per word between the two countries is carried by the Anglo-American Telegraph Company, of which I am the managing director, I am in a position to state that the statistics I have given are absolutely correct. I think it desirable to say further that there are at present five

Digitized by Google

companies, with ten cables, struggling to get a living out of the Atlantic cable traffic; four of them, to my certain knowledge, are earning no dividend, and the fifth must be having a pretty hard time of it.—I am, sir, your obedient servant, H. WEAVER, managing director."

THE BRUSH "COLOSSUS" AT WORK.—In the *Scientific American* Dr. Hale describes a visit which he paid to the Cowles Smelting Works on the occasion of the first run of the colossal Brush machine. He witnessed a pyrotechnic display which evidently excited his admiration. He says:—"The big dynamo was running at 380 horse-power, though capable of 500 horse-power when required. It was making 420 revolutions per minute, and, as the electricity was drawn off, it scintillated in a brilliant and continuous fusillade of sparks, varying in colour from white to emerald green, and occasionally flashing out in a burst of unusual splendour, yet perfectly controlled and free from danger to the spectators. The furnaces are charged with sixty pounds granulated copper, sixty pounds corundum, and thirty pounds coarse charcoal, besides the pulverised lime-coated charcoal used as packing. This mixture contains over 32 pounds of aluminum or about 54 per cent. of the corundum. Into the furnace thus charged pours the current from the colossus, fusing the almost infusible corundum like wax, causing its molecular structure to be broken up into its elements, and raising the temperature of the entire mass to a very high heat. Vent holes are left in the covering of the furnace, through which escape the liberated gases and some of the volatilised aluminum, the whole glowing with a bright flame which sometimes darts up to the height of many feet." The current is started at 2,000 amperes, and is allowed gradually to increase to about 2,400 amperes; at the same time the carbon electrodes are from time to time drawn asunder, till at last they stand wide apart, and the current flows freely through the entire furnace. The process of reduction takes about two hours. "The product appears in the form of a fused mass of metal embedded in the surrounding carbon. Most of this mass is an alloy of copper and aluminum, varying much in the proportion of the two. Mostly it exceeds the 10 per cent. of aluminum which gives the alloy of maximum strength, and is a brittle white metal, which is again fused with the addition of more copper to such an alloy as may be required. Sometimes there are found small fused rubies and sapphires. The suboxide of aluminum—never found in nature, and never before known to exist or to be capable of formation—is always present in larger or smaller quantities. I have also seen specimens of beautiful white fibrous alumina. With other charges, sub-oxides of silicon and titanium are found—very curious products indeed. The intense even heat partially fuses the carbon, and the electrodes are converted into graphite. The price of aluminum alloys has been reduced to a scale adopted by reckoning the value of the contained aluminum at 2·50dols. a pound, previous sales of that metal having been at the rate of 75 cents an ounce. The 10 per cent. alloy is said to be the strongest metal known, though alloys of a less per cent. have great utility, being tougher, but not so strong. Some specimens of the alloys made by the Colossus, which are simply cast, not wrought, have recently shown the phenomenal strength of 131,000 pounds per square inch. In the year 1885 the whole amount of aluminum produced is stated as 3,400oz., aluminum being then regarded as a precious metal. The capacity of the Colossus will enable it to reduce a larger amount than this, in the alloy with copper, within the period of twenty-four hours."

LISKEARD AND THE ELECTRIC LIGHT.—A meeting of ratepayers, convened by the mayor in response to a requisition, was held at the Guildhall, Liskeard, last evening, to consider the desirability of lighting the principal thoroughfares of the town with the electric light. After a few words from the mayor, Mr. J. Rogers, as one of the committee who arranged for the recent successful experimental lighting of the town by the electric light, explained that it was proposed to form a company, with a capital of £3,000, for the purpose of lighting the town with the electric light. One-third of the capital would be taken up by the firm of Laing, Wharton, and Down, of the second £1,000 five gentlemen had agreed to subscribe £100 each, and he believed another five would be easily found to take the same amount of shares, and the remaining £1,000 it was proposed to offer to the general public. The shareholders did not look for high dividends, but would be content with a modest three per cent. At present Liskeard paid £216 a year for the illumination of its public thoroughfares. Compared with other towns of equal size that was not an excessive amount. But for years past, from a mistaken sense of economy, the public lighting of Liskeard had been starved (applause). The promoters of the new company were prepared to light the town in a manner that would place it, in the illumination of its streets, on an equality with any town in the kingdom, but they must pay a little more for it than they were at present paying for gas. To place the public lighting of the town on a satisfactory footing, even with gas, they would require 36 additional lamps, which would involve an increased expenditure of £108 per annum, making in all £324 per year. For £350 a year the proposed new company would light all the principal thoroughfares of the town by electricity, and the remaining streets by either gas or oil. For an extra rate of 2½d. in the £, therefore, they would be able to have the principal thoroughfares lighted by electricity. With the town lighted by the electric light, he predicted that its trade would be improved, persons would be induced to come there to reside, and the ratable value of the town consequently increased.—Mr. Godfrey thought the municipality, and not a private company, ought to undertake the lighting of the town.—Mr. Wharton, replying upon the observations of previous speakers, said the electric light was being used ten or fifteen times more extensively in London that it was three or four years ago. Fewer streets, he admitted, were lighted by it, but that was because private companies undertook ridiculous contracts to light the streets by electricity at 20 per cent. below gas, and had in consequence come to grief. But the private use of the electric light had enormously increased. Nearly all the best hotels, theatres, and railway stations were taking it, and there was, in fact, hardly a large establishment that was not using it. Moreover, negotiations were in progress for a very big scheme of public lighting in London. He was prepared himself to find a third of the capital of any local company, and he would not do that if he thought he was going to lose his money.—Mr. S. W. Jenkins, as a member of the committee, testified to the accuracy of Mr. Rogers's figures, and added that the committee would undertake for £320 a year to place 18 arc lights in the principal thoroughfares, and light the rest of the town better than at present.—After some further discussion, it was proposed and seconded "That this meeting, having had placed before it the scheme proposed for the electric lighting of Liskeard, expresses its approval of the same, and recommends its adoption by the Town Council."—Mr. Ainge proposed an amendment declaring that the meeting did not feel justified in pledging itself to the increased rate which the electric lighting would involve. The mayor asked that none but ratepayers should vote. For the amendment there were 35 hands; for the resolution, 40.

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 31.)

Faraday's mode of experimenting consisted in suspending an elongated bar of the material to be tested between the poles of a powerful electromagnet. If the substance were magnetic the bar would assume an *axial* position—that is, it would set with its greatest length along the line joining the poles of the magnet. If the substance were diamagnetic the bar would assume an *equatorial* position—that is, it would set with its length perpendicular to the line joining the magnetic poles.

When a substance is not isotropic—*i.e.*, does not possess the same properties in all directions within its mass—it generally happens that the magnetic permeability is different in different directions. This is the case with most crystals which do not belong to the cubic system. In such cases the axial or equatorial setting of the bar is not a safe test to ascertain whether the substance is magnetic or diamagnetic, for a magnetic body may have a greater permeability in a direction at right angles to its greatest length and may thus set equatorially, while a diamagnetic body may have a greater magnetic permeability along its greatest length than at right angles to it, and may consequently set axially. This behaviour is known as magne-crystallic action. It is frequently exhibited by a bar of crystalline bismuth, which then assumes an axial position between the poles of the magnet

A diamagnetic substance behaves as though it had magnetic polarity induced in it, opposite in direction to that which would be induced in iron under the same circumstances. Its behaviour can, however, be imitated by suspending a bar of a magnetic substance within a liquid more magnetic than itself. In this case, the magnetic lines of force pass more readily through the liquid than through the bar, and in their endeavour to obtain a passage through the liquid for as large a part of their journey from pole to pole as possible, they compel the liquid to take the axial position, and the bar being pushed out of the way, is compelled to assume an equatorial position. Hence it has been inferred that diamagnetic phenomena are due to a differential action, and that all bodies, as well as vacuum, are acted upon in the same way by magnets, and have the same polarity induced in them, but that diamagnetic substances are those in which the action is less strong than in vacuum. This hypothesis accounts perfectly for the apparent polarity of diamagnetic substances. There is, however, one objection against the hypothesis. If a ray of plane-polarised light be made to pass through a transparent substance which is surrounded by a coil through which an electric current is flowing, the light passing parallel to the axis of the tube, the plane of polarisation will be turned round through an angle depending on the number of turns of wire in the coil, the strength of the current, and the nature of the transparent medium. If the medium be diamagnetic, the rotation is in the direction of the current. If the medium be magnetic, the rotation is in the opposite direction. In a vacuum, no rotation has been detected. This result indicates a difference in *kind* between magnetic and diamagnetic substances, and not simply one of *degree.*

If a bar magnet be suspended so that it can turn freely in all directions about its centre of gravity, it will set with its magnetic axis in the direction of the magnetic lines of force, supposing these lines to be sensibly parallel throughout the portion of space occupied by the magnet.

If such a magnet be exposed to the action of the earth alone in London, it will set with its magnetic axis inclined at an angle of between 67° and 68° to the horizon, the north end being the lower, while the vertical plane through the axis of the magnet will make an angle of about 18° with the geographical meridian, the north pole of the magnet pointing to the west of the geographical north.

Def. The vertical plane through the magnetic axis of a freely suspended magnet or compass needle at rest is called the magnetic meridian.

Def. The angle between the magnetic meridian and the geographical meridian is called the declination. By sailors it is more generally called the variation of the compass. It is reckoned east or west, according as the compass needle points east or west of true north.

Def. The angle which the magnetic axis of a magnet, capable of turning freely in all directions about its centre of gravity, makes with the horizon is called the *inclination* or *dip.*

The declination and dip are both found to vary continuously over the earth's surface. A line passing through all points for which the declination is the same is called an *isogonic* line; a line passing through all points for which the dip or inclination is the same is an *isoclinic* line. With a set of maps showing these lines for every degree, the mean declination and dip at any point of the earth's surface can be determined. At the magnetic equator, which does not coincide with the geographical equator, the dipping needle is horizontal. South of the magnetic equator the south pole of the needle is inclined downwards. At the magnetic poles the needle is vertical. The pole of the earth situated in the northern hemisphere is, of course, a south magnetic pole, since it attracts the north pole of a magnet. Sometimes the north-seeking and south-seeking poles of a magnet are called the austral and boreal poles respectively.

The declination and dip are not, however, constant at any place. Besides the irregular and great variations which occasionally take place, and which are known as magnetic storms, there are three principal changes in the declination, known respectively as the diurnal variation, the annual variation, and the secular variation.

The secular variation is a slow, steady change, which continues in the same direction for many years. Thus in 1580 the compass needle in London pointed 11° east of north. This declination diminished until the needle pointed due north in 1657, but continued moving westward till it attained its maximum westerly declination of 24° 27′ in 1816. Its declination is now about 18° 19′, and is decreasing at the rate of about 7′ per annum. The inclination attained a maximum of 74° 42′ in 1720, and since then has been steadily diminishing.

The daily variation consists of a very slight westward motion from 7 a.m. till 1 p.m., followed by an easterly motion which continues till about 10 p.m. In the summer this is followed by a second, though smaller excursion, westward, commencing at midnight, the needle returning before 7 a.m.

The annual variation consists in a change in the declination and dip, and in the intensity of the magnetic force, which change goes through all its phases in the course of a year. In the Northern Hemisphere the change of declination is westerly from May to September, and easterly from September to May. The total force attains a maximum in June. The reverse is the case in the Southern Hemisphere.

Def. The magnetic *intensity* (total intensity) at any point of a magnetic field is the force which would be exerted upon a north magnetic pole of unit strength placed at that point.

A magnetic field is completely known if we know the direction of the lines of force and the magnetic intensity at every point of the field.

Def. The *horizontal intensity* of the earth's magnetic force at any point is the horizontal component of the force exerted upon a north magnetic pole of unit strength placed at that point.

Def. The *vertical intensity* of the earth's magnetic force at any point is the vertical component of the force exerted upon a north magnetic pole of unit strength placed at that point.

The total intensity is, of course, the resultant of the horizontal and vertical intensities. Hence, of the four quantities, horizontal intensity, vertical intensity, total intensity, and dip, if any two be given the others can be found from the parallelogram (or triangle) of forces. Thus, if these quantities be denoted by H, V, I, and δ, respectively, we have,—

$$I = \sqrt{H^2 + V^2},\ V = \sqrt{I^2 - H^2},\ H = \sqrt{I^2 - V^2},$$

$$\sin \delta = \frac{V}{I},\quad \cos \delta = \frac{H}{I},\quad \tan \delta = \frac{V}{H}.$$

If a compass needle be brought near to the north pole of a large magnet its south pole will be attracted and its north pole repelled. Hence the needle will turn so as to present its south pole towards the north pole of the magnet. But its south pole being nearer to the pole of the magnet than its north pole the attraction will exceed the repulsion, and the needle will be bodily attracted. If the needle be placed in a

Digitized by Google

uniform magnetic field the forces on its poles will be exactly equal and opposite, and, consequently, while the needle will be made to take up the direction of the lines of force it will have no tendency to move as a whole in one direction or another. Such a field of force is produced by the earth in any space of moderate dimensions. For example, there would be no sensible difference either in direction or intensity in the magnetic force of the earth within the space of an ordinary room, and the forces exerted by the earth upon the poles of any ordinary magnet will be equal and opposite, since both poles of the magnet may be considered as equally distant from the earth's magnetic poles. Hence the earth's horizontal force will have no tendency to move a compass needle horizontally as a whole, and its vertical force will have no tendency to move the needle vertically. Thus the apparent *weight* of a steel bar will be unaffected by magnetising it, and the action of the earth will be a *directive* action only. If a magnet be placed on a cork which is floating in water the magnet will take up the direction of the magnetic meridian, but there will be no tendency for the cork to move in any direction through the water.

But if a steel bar be accurately balanced about its centre of gravity and then magnetised, it will, as above stated, take up the line of the magnetic dip. If we wish the bar to remain horizontal while it is free to turn in the magnetic meridian we must balance it about an axis which in northern latitudes is nearer the north end of the bar than its centre of gravity is, and in southern latitudes is south of its centre of gravity. It is only at the magnetic equator that the bar will remain horizontal when free to turn about its centre of gravity. Compass needles are generally balanced about a point considerably above the centre of gravity, like the beam of a balance which has great stability. This prevents their dipping sensibly under the action of the vertical force.

(To be continued.)

IMPORTANT TESTS OF ENGINES.

We have always been amongst those who contended that trials of engines conducted by unbiassed parties were extremely valuable, not only to the makers of those engines but to the community at large. When the Royal Agricultural Society discontinued its annual trials England stood undoubtedly in the foremost position as engine makers in the world. Since then competitors have taken the designs from our best known firms and have followed in their footsteps. Emulation, more or less, ceased between these eminent firms, and it was generally feared that England had not made the progress she ought to have made. We are not at all sure that this conclusion is correct, and we think the important trials which took place just before the close of the Colindries will go far to restore the confidence of Englishmen, and to assure them that they are not yet reached by any of their Continental rivals, so far as thoroughly good workmanship and economy are concerned. We heartily congratulate Messrs. Paxman and Co. for having come forward voluntarily and allowed the public to obtain perfectly trustworthy and satisfactory tests of the engines which have been running and doing good work for the past three years at the South Kensington Exhibitions. Our space is far too limited to enter into any discussion of the figures in the present article, so that we must content ourselves with giving as full information of the trials as possible, leaving the figures and diagrams to speak for themselves. It will be seen that the trials were carried out by Mr. W. E. Rich, M.I.C.E., and Prof. Kennedy, M.I.C.E, with an able staff of assistants. The reputation of these gentlemen is second to none as regards ability to take tests, and the results obtained by these absolutely independent authorities must be taken to be as nearly accurate as modern science can make them. Two separate reports have been made of these tests, one by Mr. Rich, and the second by Mr. Rich conjointly with Prof. Kennedy. We give below a few paragraphs from the former of these reports, and the whole of the conjoint report, the latter dealing more especially with the tests, the former containing more general references. Among other things, Mr. Rich says:—

"The results of the trial detailed in the following report must tend largely, I think, to confirm the good opinions of the public regarding engines of this type.

"The engines, when you first introduced me to them officially on the 20th of October last, were driving two dynamos for electric lighting purposes at the Colonial and Indian Exhibition, and I learned from you that they had been working steadily day after day through three successive Exhibition seasons, on similar duties, without any material repairs or overhaul, that no special overhaul of them had been made for preparing them for the present trial, which took place at the end of an Exhibition season, and that consequently the present test might be taken as that of such engines in current working condition. . . . I understand your instructions to me to be that you would place the engines, with the ordinary fireman and engine driver, unreservedly under my control, and that you desired me to carry out the most perfect test of their economical performances (especially in steam and coal consumption) which was practicable during the seven hours' run of their ordinary daily duty when driving the two dynamos. . . . We provided ourselves for the purposes of the trial with a powerful staff of assistants, so that all important records were at least doubly checked, and we divided the work of supervision in the following manner:—For the operations of starting and stopping under the most uniform condition of coal on fire, water in boiler, steam pressure, &c., to which the greatest possible importance in such trials must be attached, we both attended in the stoke hold, and checked the facts and figures carefully with one another.

"In the interim, during the currency of the trial, I devoted attention to the general control of it, the measurement and official logs of coal, feed water, steam and water gauges counter, temperatures, &c., while Prof. Kennedy directed the staff, taking and reducing the indicator diagrams; and at a table placed near the engines he plotted the records and results, with curves of increments and averages, as fast as we obtained them, so that any irregularity would have been noticed immediately, and I cannot speak too highly of the value of keeping such records up to date in such a trial.

"The day was damp, indeed it was raining during the afternoon, and the steam pressure was less than that at which you desired to work. I am not prepared to give an opinion as to the amount of loss due to damp weather, but it is generally considered by practical men to be prejudicial to such a trial, and no doubt 115lb. steam would have given somewhat higher results than 107lb. In case the way in which the intermediate records during the currency of the trial have been tabulated and recorded graphically should be criticised as being unnecessarily elaborate, and leading to useless work in reductions, &c., I would have it understood that I attach great value to these frequent statistics, as they evidence distinctly whether the trial has proceeded fairly and uniformly, they enable sub-trials within the main trial to be criticised, and sometimes when an unexpected hitch occurs, stopping a test altogether, a short trial of sufficient length to give valuable information may be taken out of the incompleted records. The most difficult matter in such a trial is to get the fire uniform at the beginning and the end. The curves of increment—see Appendix E—are the best check on this. The longer a trial is, the less the error from such lack of uniformity.

"The variation of the coal consumption even in the long intervals shown near the top of the curve sheet, Appendix E, shows how little value can be attached to the reputed coal consumption, when the trial is of very short duration.

"I now beg to hand you the following joint report by Prof. Kennedy and myself on the trial and its results.—I remain yours very truly, (Signed) "WILLIAM E. RICH."

Westminster, S.W., Nov. 15, 1886

Jas. Paxman, Esq, Colchester.

DEAR SIR: In accordance with your request, we, on 27th October last, carried out a trial of the economic performances of your 40 horse-power semi-fixed compound engines, which were

Digitized by Google

then driving two dynamos in the south-west corner of the electric light shed at the Colonial and Indian Exhibition.

The cylinders and working gear of these engines are fitted to a bed-plate placed beneath the barrel of the boiler, the cylinders themselves being side by side under the smoke-box.

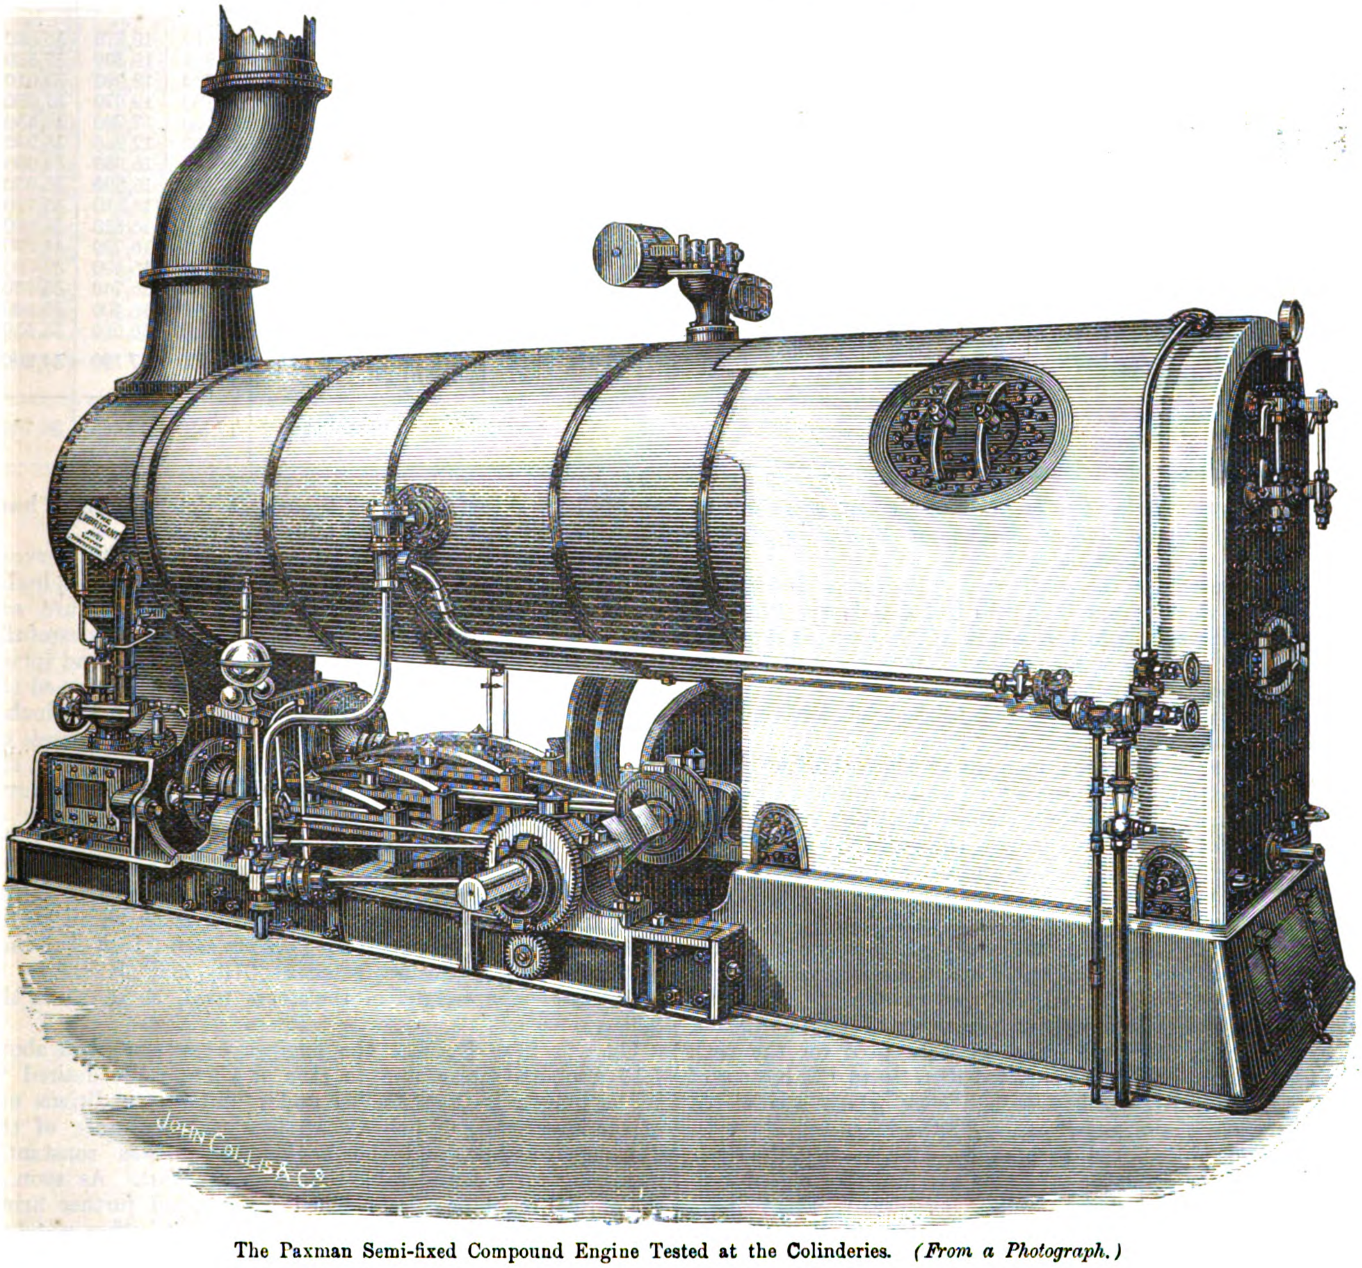
The cylinders are fitted with steam jackets, but at the time of the trial no steam was admitted to the jacket spaces, which were supposed to be full of dry, warm, stagnant air, which would act as a non-conductor. The external cylindrical surfaces are lagged, and the boiler shell is coated with non-conducting composition.

The admission of steam to the high pressure cylinder is regulated by a gridiron valve, the stroke of which is controlled

Barrel of boiler, 4ft. 5in. diameter, 12ft. 8in. long, over smoke box.

Heating surface in firebox	88 sq. ft
„ tube surface 100 tubes, 2¼dia., outside, 10ft. 7in. long between tube plates	623 „ „
Total.....................	711 sq. ft.
Firegrate (ordinary) 5ft. long × 3ft.10in. wide...	= 19·2 sq. ft.
Firegrate reduced size for trial, 4ft. 7in. × 3ft. 4¼in.	= 15·3 „ „
Firegrate air spaces between bars, total	= 4·56 „ „

Chimney, 17in. diameter.



The Paxman Semi-fixed Compound Engine Tested at the Colinderies. *(From a Photograph.)*

by the governor which actuates a block in a suspended link. The exhaust valve for the high-pressure cylinder and the main slide valve of the low-pressure cylinder are placed in an intermediate receiver between them.

The following are the leading particulars of the engines furnished to us by your firm :—

High-pressure cylinder, 12¼in. diameter × 24in. stroke.
Low-pressure „ 20in. „ × 24in. „
Steam stop valve, 3in. diameter.
Exhaust nozzle, 4⅜in. diameter.
Steel locomotive boiler, 18ft. 4in. long over smoke box.

The boiler is proportioned for a working pressure of 120lb. to 140lb. per square inch, but at the time of the trial the safety valves began to blow at 115lbs. per square inch.

To be precise, we had the cylinder covers removed after the trial, and personally verified the strokes and diameters. The strokes are as stated above, but the high-pressure cylinder diameter is now 12·28in., and the low-pressure 20·03in. diameter, the barrels having worn slightly from continuous use, but being in excellent order. The co-efficients used in calculating the power from the diagrams are based on these figures, after allowing for the piston rods, which are 2¼in. diameter. Previously to the trial we examined the pipe con-

nections about the boiler and engines, to see that there was no connection with other boilers, and at our request the injector and its pipes were disconnected.

The coal used on the trial was "Radford's Navigation Welsh Steam Coal," from Radford's Hafod Colliery, Rhondda Valley, and it was weighed in lots of 100lb. each, as the trial proceeded, on a new weighing machine, which was verified by us, both before and during the trial.

Each lot of 100lb. was charged on to the fire before the next lot was served out on to the stoking floor.

Throughout the trial, the moment at which the first shovel full of each 100lb. of coal was served on the fire was signalled by a sharp whistle to the whole staff by Mr. Rich, and records of the condition of all the gauges, the counter, and the feed water consumption were then taken simultaneously and recorded in the official log.

The feed was measured in a rectangular tank in which we had fitted a float gauge, so that at any moment we could see how many pounds weight of water had been previously served into the boiler. The float scale was graduated by us by pouring into the tank successive quantities of water of 60lbs. each, weighed in the same scales as were used for the coal. The feed suction pipe was connected directly to the bottom of this tank, and was furnished with a cock which was closed precisely when the float fell to the 800lbs. mark.

We found pipes fitted to each cylinder, so that the cards from both ends could be taken on one indicator placed midway between them, but our joint experiences told us that we could not hope to get reliable results taken in that manner, and we consequently had the pipes removed, and placed two "Darke's" indicators close to the respective ends of the high-pressure cylinder, and two "Richards" indicators on the ends of the low-pressure cylinder. The former had $\frac{1}{48}$ springs in them, and the latter $\frac{1}{20}$ springs. The instruments and springs were all supplied by us, and had all been tested comparatively recently.

The four diagrams forming a set were taken simultaneously, as nearly as possible in the middle of the interval between the times at which the successive lots of coal began to be charged on the fire, as shown in the log. The indicator cards were measured in the first place during the trial by ordinates, but subsequently, to be more precise, they were remeasured with a carefully tested planimeter, which gave results 1·8 per cent. less, and these last determinations have been adopted in the enclosed tables and records.

At an early period in the trial we were somewhat nervous that the pressures at the back of the high-pressure cylinder were imperfectly indicated, as the initial steam pressure was much lower than at the front end, but the matter was carefully investigated by Prof. Kennedy, and the indicator and spring were changed twice over, with results which confirmed the accuracy of the previous diagrams. Scales graduated in inches and decimals were placed against the water gauge glasses on the boiler front, so that the variations of water level in the boiler could be recorded precisely. The alterations of level in the gauges were very gradual throughout, without any of the rapid alterations sometimes noticed on such trials. The steam supplied to the engines was apparently remarkably dry all day. The area of the boiler at mean water level during the trial was measured, and the weight of water in it, at the mean steam temperature, corresponding to each 1-10th of an inch on the scale, was thus estimated at 31lb., and allowed for in determining the weight of the steam used, as shown in the tables.

On the 27th October the engines were started at about 7:15 a.m., and were due to stop at 4 p.m. We desired to get as long a trial as possible under uniform conditions out of the intervening 6¾ hours. At first the resistance of the dynamos was low, and the engine power was constantly increasing for a considerable time after the start. As soon as the normal resistance was reached we stopped further firing and feed, swept the stoking floor clear, and together watched the pressure gauge till from the lowering of the fire (which we also inspected from time to time) it fell to 100lb. per square inch. At that moment, viz., 10:12 a.m., the first signal was given, the counter, which stood at 0, was thrown into gear, the gauges were all noted, and the first shovel full of the first 100lb. lot of coal was put on the fire. The feed tank was full, and shortly afterwards we began to charge measured feed water into the boiler, and at 10:20 the first set of diagrams was taken. Records at frequent intervals, as described above and shown in abstract log of trial, followed for 5 hours 42 minutes. At 12:30 the fireman began to use some of the few ashes which had accumulated in the ashpit since the start. At 3:26 we told him that the 100lb. lot of coal then commenced would be the last served out to him,

Indicator Cards, Set VIII. 12:52 p.m.

Expanded Indicator Cards. The ordinates of each card in this figure are the means of a pair (front and back) of actual indicator cards. The length A B, represents the volume of steam, at boiler pressure, corresponding to the measured feed water per (single) stroke. The line, B C, is the theoretical (adiabatic) expansion curve for this quantity of steam in a single unjacketted cylinder. Scale of volumes=0·4 of cubic ft. to ½in.

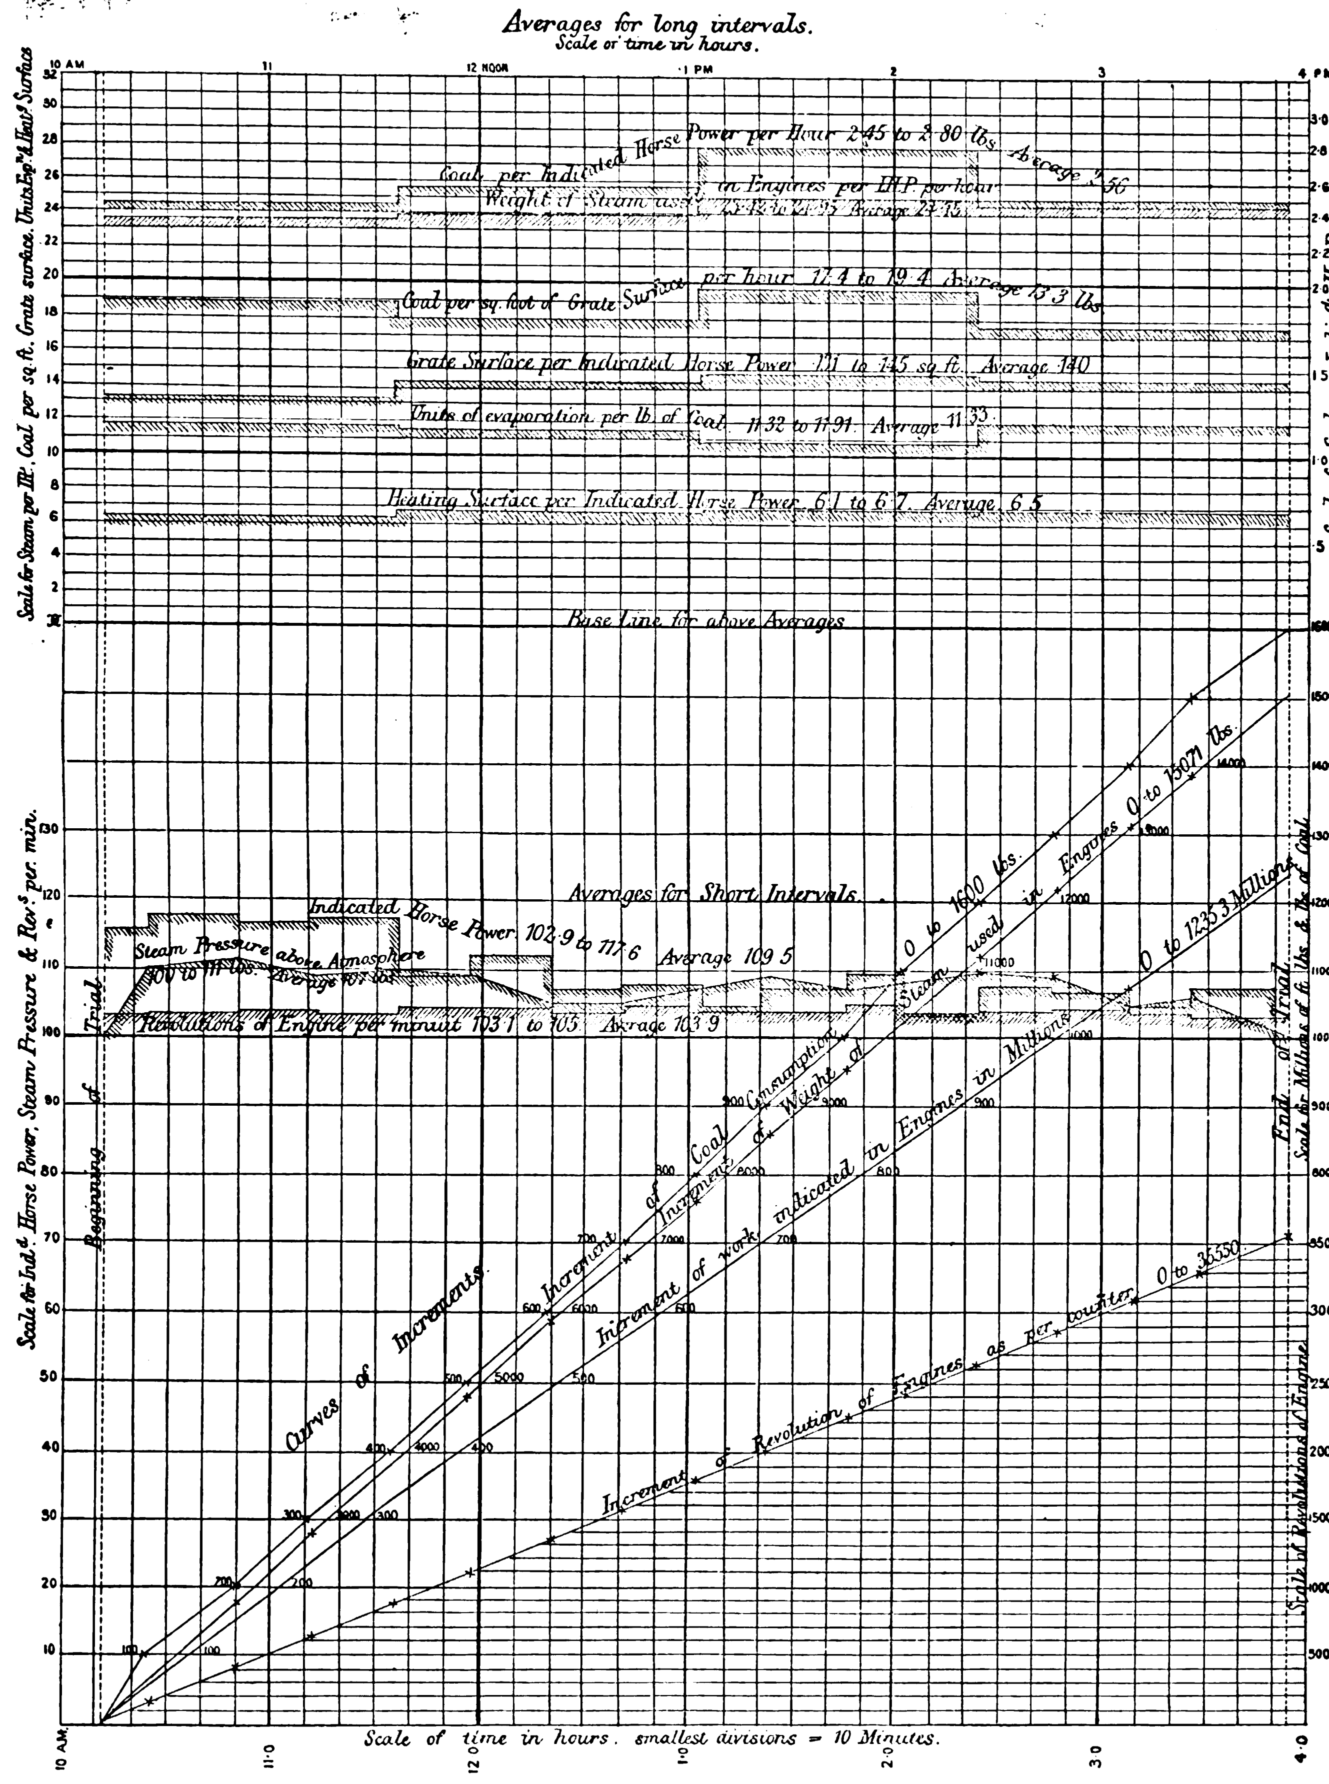
APPENDIX E

TRIAL OF DAVEY PAXMAN & C^os SEMI-FIXED COMPOUND ENGINE.



and that he must make the most of it and the ashes which remained. At the same time we arranged so to adjust the feed service as to get back the water in the boiler as nearly as possible to the level at which we started. When at last the fire became unequal to make the steam demanded by the engines, the steam pressure began to fall, and we together watched it narrowly till, on its reaching 100lbs. exactly, the final signal was given, the counter was pulled out of gear,

Digitized by Google

the gauges and water tank consumption were all taken, and the trial was at an end, viz., at 3:54 p.m., having lasted 5 hours 42 minutes.

During the whole trial the engine power, speed, steam pressure, &c., were remarkably uniform, the steam was dry, and there was no hitch or inconvenience of any kind from beginning to end. No handle about the engine was touched, excepting that on the feed suction cock and the water gauge cocks; the steam starting valve was wide open, the speed being controlled solely by the governor. The fireman regulated his fire and the feed water to meet the current requirements of steam.

Beyond the observations recorded our assistants took many intermediate records, which on being plotted have been found to further confirm the accuracy of those given in the official log. The logs and results are given *in extenso*:—

In Appendices

A. Table 1, Abstract Log of Trial.
B. Table 2, Result of Trial.
C. Specimens of indicator diagrams.
D. Expanded diagrams with a diabatic curve.
E. Diagrams showing curves of increments and averages and the general results of the trial graphically.

The following is a summary of the results:—Duration of trial, 5 hours 42 minutes = 342 minutes, or 5·7 hours.

Totals.

Revolutions, 35,550.
Coal served on fire = 1,600lb.
Weight of steam used in engines = 15,071lb.
Foot-lb. of work indicated = 1,235·3 millions.
Number of sets of indicator diagrams, 17.

Averages.

Steam pressure in boiler = 107lb. per sq. inch.
Revolutions per minute, 103·9.

Indicated pressure in high-pressure cylinder ..	37·2
Indicated pressure in low-pressure cylinder...	13·89
Indicated horse-power, high-pressure	54·6
Indicated horse-power, low-pressure	54·9
Total	109·5
Weight of steam used in engines per indicated h-p. per hour	24·15lb.
Coal burnt per 1 h.-p. per hour	2·56lb.
Water evaporated per lb. of coal	9·42lb.
Mean temperature of feed	55·5°
Units of evaporation or equivalent weight of water at 212° evaporated at 212° per lb. of coal	11·33
Calorific value of coal used as per mean of 6 experiments with calorimeter at University College	13·9
Efficiency of fireman, furnace, and boiler $\frac{11·33}{13·9}$	815.
Coal burnt per square foot of reduced grate per hour	18·3lb.
Grate surface per indicated h.-p.	·14 sq. ft.
Heating surface „ „	6·5 sq. ft.

The above results speak for themselves. We consider them eminently satisfactory for high-pressure engines in regular work without any special preparation for trial.—We remain, Dear Sir, Yours faithfully,

(Signed) William E. Rich, M.I.C.E.
Alex. B. W. Kennedy, M.I.C.E.

The Electric Light in Austria.—We learn from *Industries* that the town of Graz, the capital of Styria, is to have its streets lit by electricity, power being obtained from the River Mur.

South of England Telephone Company.—The directors of this company, at their meeting yesterday, declared a dividend of 6 per cent. per annum on the preference shares of the company, for the half year ending 31st October.

NEW ZEALAND CABLE TARIFFS.

The following correspondence speaks for itself. It will be seen that the suggestion of Sir Dillon Bell has been accepted. It speaks volumes for the desire of the Eastern Extension Company to meet the wishes of the Australian and New Zealand authorities, and the wants of the telegraphing public, in that authorisation has been given to refund the extra charges due to the raising of the tariff:—

Sir Julius Vogel, Wellington, to Chairman Eastern Extension Company.

20th November, 1886.

15th November. If Press guarantee can be satisfactorily arranged, I will agree to *status quo ante.* Have instructed Dr. Lemon to endeavour to arrange with your Superintendent on basis that Australian Press arrange with you direct or through Sydney Government. Reuter makes his own arrangement, and we act as sponsors for Press Association. We understand Press message same meaning as hitherto, code words mixed with plain ones.

Chairman Eastern Extension Company to Sir Julius Vogel, Wellington.

23rd November, 1886.

Your telegram fifteenth only received yesterday, owing to derangement of service by cyclone in India. The proposal to revert to *status quo ante* for six months was Sir Dillon Bell's suggestion, and with view to meeting interests and convenience of telegraphing public Company accepted it. The reduced rate for Press with guarantee was your suggestion, and we accepted it on condition that your Government ensured the guarantee. As, however, the removal of deadlock is so essential to telegraphing public, Company will not on account of any difficulty with Australian Press delay reverting to *status quo ante* as proposed by Sir Dillon Bell, and will accept your Government's guarantee for Press Association at once, and you may then be able to arrange the guarantee in regard to Australian Press and Reuter during next six months. It must be distinctly understood that Press telegrams are to be wholly in plain language in accordance with the rules laid down when two shillings and eightpenny rate for International telegrams and other special rates were arranged. Code language has never been permitted over any lines in Press telegrams carried at reduced rates.

Chairman Eastern Extension Company to Postmasters-General Victoria, New South Wales, and South Australia.

23rd November, 1886.

I forward you copy of telegram which I have to-day addressed to Sir Julius Vogel, and which practically removes the deadlock for present. I hope before the six months expire that the New Zealand connection with Australia will be put on a satisfactory footing for the future. I also hope that the Australian Governments will see the desirability of considering the Company's guarantee proposal, as it would give the colonies complete control over telegraph system, and enable them to make the rates what they please.

Agent, Melbourne, to Eastern Extension Company.

23rd November, 1886.

Postmasters New South Wales and South Australia ask Chairman to authorise reverting to New Zealand former tariff for ordinary messages, pending settlement of Press guarantee.

Chairman Eastern Extension Company to Postmasters-General Victoria, New South Wales, New Zealand, South Australia, Queensland.

24th November, 1886.

In continuation of my telegrams of yesterday, and to make the *status quo ante* complete, I authorise you to refund to the senders of messages the additional charge of 4s. collected for the New Zealand Cable since the 1st November.

THE JUBILEE OF THE ELECTRIC TELEGRAPH.

Preparations for celebrating the QUEEN'S JUBILEE have called to mind the fact that the year 1887 is the fiftieth anniversary of the ELECTRIC TELEGRAPH. In 1837 was erected the first telegraph line, which became the parent of all the telegraph lines that are now in existence. The line was a very short one, extending only from London to Blackwall, and it was regarded, at all events by lookers on, as a mere experiment. In an encyclopædia published about that date the cautious remark is hazarded that "several interesting trials have been made to test the practicability of conveying intelligence with the speed of lightning by means of galvanism." A promise is made that "these will be explained in the supplement of this work;" but as the promise was not redeemed we may infer that the learned compilers of the work in question, who devoted a whole column to the subject of telegraphic signalling by mechanical appliances, had not even at the termination of their labours formed any sanguine estimation of the scheme for signalling "by means of galvanism." And it is no doubt a fact that for some few years subsequent to the year we have named, the difficulty of finding capitalists to take up the idea prevented its getting much beyond the experimental stage. Nevertheless, the Blackwall telegraph line was a complete success; it demonstrated for the first time and beyond all question the practicability of electrical signalling; and in that very year—the year of the QUEEN'S Accession to the throne—we must fix the first birthday of the ELECTRIC TELEGRAPH.

Whether the Jubilee of this noteworthy event would have been allowed to pass without any public notice is more than we can say; but as the QUEEN'S JUBILEE has reminded us of it, we are strongly of opinion that the occasion ought to be marked in some appropriate and adequate fashion. Later on we may indicate more specifically in what way this should be done; but for the present we need only remark that any befitting scheme that may be set on foot will almost certainly have the cordial support of the public, not only in England, but in her Colonies, and perhaps also in America and on the Continent. The immense importance of the electric telegraph is nowadays universally recognised. No invention of modern times can pretend to outdo it in point of utility; and the only rival to be compared with it would have been paralysed in its progress but for the aid which the electric telegraph has rendered it. As instruments of civilisation, of commerce, and of universal good fellowship, the railway and the telegraph have worked hand in hand; and the world now, perhaps, could as ill spare the one as the other. Locomotion has immensely developed in the course of these fifty years; but the telegraph, if possible, even more. In the notice from which we have already quoted, we are told that at that time "Twenty-seven telegraphs convey information from Paris to Calais in three minutes." This was sharp work for semaphore signalling, even if the information was only two or three movements of the indicating arms, which had to be translated by means of the "telegraphic dictionaries" of those days. But to-day one electric telegraph does the same amount of work over thrice the distance in less than as many seconds. It is as popular as it is useful; and when the time approaches for celebrating its half-century there will be no lack of sympathising friends outside the profession most closely identified with the construction and maintenance of electric telegraph lines.

Confidently leaving this particular aspect of the subject to future consideration, we would now ask leave to call more particular attention to a matter nearly related to it which will not bear to be postponed. The time for electing the President of the SOCIETY OF TELEGRAPH-ENGINEERS and ELECTRICIANS is fast approaching, and whatever selection is then made will have to hold good during the session of 1887. Now, it is obvious that this Society must take a prominent—and ought, indeed, to take the leading—part in any organised effort to commemorate the TELEGRAPH JUBILEE in a becoming manner. The choice of a President on this occasion is, therefore, a matter of considerable importance, and one that ought not to be settled hastily, or necessarily on the ordinary lines. Indeed, to follow ordinary precedent on an extraordinary occasion like the present would betray a slavish adherence to custom, or a want of moral courage, which we could not help regarding as reprehensible. A special selection should unquestionably be made in the special circumstances anticipated for next year; and the Society should cast about it carefully to obtain the services of a President who will not only represent it with dignity, but conduct its affairs with energy and discretion. If the routine of rotation has brought

Digitized by Google

round an officer of the Society who will meet these requirements, all the better; but if there be the least doubt about it, we strongly recommend the Council to disregard routine for once in a way, and fearlessly decline to nominate the wrong man.

To the question: What is the right sort of man? we have already replied as plainly as possible: *Who* he may be is not for us to say. There is a choice among several different sets of representatives—the representatives of electrical science, the representatives of historic telegraphy, the representatives of the Society. As regards their relative claims to the presidency during the Jubilee Year there is, perhaps, not very much to choose between them. A choice might be made from any one of them, providing the person selected be a suitable one. Perhaps the least suitable class to select from would be the purely scientific. It does not exclusively represent electric telegraphy, and in a general way is too much preoccupied to furnish the practical business aptitude which is wanted for the purpose in view. Among the second class there is a better field of choice; but on that very account it may be feared that rivalries and jealousies might create difficulties not easily surmounted. The original inventors of the telegraph are no longer among the living. Who shall represent them now? It may be much easier to answer a question of that kind than to preside over a distinguished society during an eventful period of its existence; and different people would, we fear, have different answers to offer. From the Society, as a society, there might be less difficulty in making an excellent choice, and about which there need be no heartburnings or humiliations. To illustrate our meaning we may mention for example, Sir F. Bolton, who was one of the principal founders of the Society, and who now occupies a position which places him above the suspicion of rivalry and outside the range of jealousy. We name him only by way of indicating the sort of President the Society requires for the coming year, and of escaping some of the personal and professional difficulties which otherwise may lead to the election of a President not in all respects desirable for an occasion like that with which the SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS will have to deal.

PROPOSED ATLANTIC CABLES.

Twenty years ago, in July, 1866, the shores of the Atlantic were permanently linked, and since that time the Old and New Worlds have been in communication with each other. Two months later, in September, 1866, the second link was completed. At the end of twenty years no less than ten cables are at work underneath the waves of the North Atlantic, and we have been somewhat surprised during the past week to see a new company announced having for its object the laying of other cables across the Atlantic. We should be glad to be able to say that the progress of twenty years had been so rapid that the capabilities of existing cables were tested to the utmost; but, unfortunately, the contrary is the case, although at the present moment the rates are very low. The capacity of existing cables is far in excess of the requirements. The investing public require to have this fact very clearly set forth, so that they may, putting the glamour of prospectuses aside, be able to judge as to the suitability of the investment. The total telegraphing business across the Atlantic is not difficult to ascertain. The managing director of the Anglo-American Telegraph Company, in a letter to *The Times*, gives the total amount at the 6d. per word tariff as £300,000, and we have no reason to suppose that he is in error. The new company does not propose to offer any greater facilities to the telegraphing community than the existing cable companies offer, and therefore in the nature of things it cannot expect to do more than get a moderate share of the business. Why a new company should get any business is difficult to understand in face of the fact that any business must be from the clients of the other concerns, to whom no inducement for change is offered.

We will now deal with the question of capital, which as dealt with in the prospectus is somewhat misleading. It is said that the existing companies, with ten cables, have a capital of about £14,000,000. That is so from one point of view—the balance-sheet—and only from that point of view. The investor's point of view is, What will £100 stock cost? And if £100 stock costs £40, the concern paying 2½ per cent., it really means that the investor gets something like £5. 12s. 6d. per cent. on his investment. In other words, it makes little difference what the capital is *said* to be, the vital point is its market value. Now, the market value of shares in Atlantic Cable companies is not an inviting one. They stand at a heavy discount, probably, taken all round, at more than 50 per cent. The market value, then, of the paper capital is less than half that stated in the prospectus. But, after all, what does it matter as to market or paper value if, at the existing rates, *no dividend is earned?* The capital might as well be £0. 0s. 0d. as any other amount. We should be delighted to be able to support new schemes of this kind, inasmuch as if the cable companies were in a prosperous condition it would also mean that the general trade of the country was more or less prospering. Even with increased business it is evident that cables cannot be worked remuneratively at too low a tariff. We have not entered into this question in any but a general manner, as we think the investing public is too familar with the existing state of the cable companies to venture into a new concern with almost absolute certainty that all the conditions are unfavourable to its success.

CORRESPONDENCE.

THE CHARACTERISTICS OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Bosanquet, in his letter to you under the above title, claims to have already, four years ago, developed a theory of magnetic circuits having substantially the same outline as mine. I have not the slightest wish to enter into a dispute as to priority, and am perfectly willing to admit that Mr. Bosanquet, Prof. Rowland, and many more have studied the magnetic circuit long before me. But allow me to ask your correspondent why he did not apply his investigations to the practical purpose of teaching us how to design dynamo machines? Had he done so four years ago, I and many of my professional colleagues would have been extremely grateful to him. It is all very well to write highly scientific papers for the Royal Society; but I claim that it is still better to write and publish in such manner that those who run (in the race of practical development) may read and learn; and I hope in future Mr. Bosanquet will give us the benefit of his scientific investigations immediately they have resulted in practical formulæ, and thus secure his claims of priority in an unmistakable manner.

The units I employ are a terror to him, and he actually requires the use of logarithms to work out the ratio of 6,000 to the number of square centimetres in a square inch. He evidently thinks that, since the scientists have settled that the C.-G.-S. system is the basis of their calculations, it is very wrong of me to employ another system of measurements. My defence is that units of measurement are simply a means to an end, and that such units will be best for practical work which fit in with the measures employed in our engineering shops. I for one should be very glad if the metrical system were adopted throughout the English engineering profession, but until this

Digitized by Google

is the case it would obviously be impossible to talk to our workmen of centimetres and grammes. The drawing of a dynamo must therefore be dimensioned in inches, and the weights must be given in pounds or cwts. Mr. Bosanquet will, I think, agree to this; and the question is therefore narrowed down to the following:—Should our calculations be made in a different system of measurement from that of the working drawings? I am strongly opposed to such practice, because each change of units increases the probability of error. Moreover, with the units I use the figures are all of reasonable magnitude, and therefore within the power of conception of an ordinary engineering mind. Can the same be said of the C.-G.-S. system? The figures are so large that it is difficult to form a correct idea of their magnitude. Is it not easier to say "the total useful field of this dynamo contains two thousand lines," than "one million two hundred thousand lines?"

Mr. Bosanquet is curious to know how I measured the magnetised section in my wire armature, which he considers a matter of the greatest difficulty. The question is strange because of its very simple solution, but as it would be discourteous to leave it without an answer I will just mention that for the purpose of such measurements I generally employ an instrument familiarly known as a "two-foot rule," and having ascertained the area filled by wire I multiply it by the ratio of π to 4, in order to allow for the waste space between the wires. When discs are employed I clamp an equal number of naked and insulated discs in a vice, and ascertain the ratio of space occupied by insulation by direct measurement.—Yours, &c., GISBERT KAPP.

[We are glad to welcome Mr. Kapp's protest against the C.-G.-S. system, and trust that others may follow his example. We have long held that the C.-G.-S. system is out of place in the workshop, and shall heartily support any movement towards a suitable system.—ED. *E.*]

SECONDARY GENERATORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: During the year 1882, being then in Boston, Mass., I carried out a series of experiments upon the use of the induction coil for the purpose of supplying electrical energy from central stations. As a result of these experiments I made an application to the United States Patent Office. The application was filed on the 29th January, 1883, and contained a complete description of a system, in which alternating or undulating currents of high tension, generated in a central station, are used in combination with induction coils, which transformed the electric energy conveyed by the mains into a number of currents of low tension and large quantity. Various arrangements were described and shown in the drawings.

The substance of this rather lengthy application may best be seen from one of its claims, which reads literally as follows:—

"The combination in a system of electrical distribution of a generator adapted to produce electric currents of high E.M.F., a continuous conductor, including the primaries of a series of inductoriums, and forming an internal circuit for the said generator; and a series of secondary circuits, each including one or more electric lamps, and formed of the secondary circuits of the said inductoriums, whereby the high-tension currents flowing in the main conductors and primaries are enabled to develop secondary currents of low tension and great volume in the secondary circuits, substantially as and for the purpose described."

The application was rejected, and the objection of the Patent Office commenced as follows:—"Applicant should demonstrate more clearly to the office the possibility of producing quantity currents from intensity currents by means of an induction coil; it is not apparent how applicant in any case can get more quantity from a secondary coil than he has in his primary."

I now find that a patent has been granted to Messrs. Gaulard and Gibbs on the 26th October, 1886, of which the first claim reads as follows:—

"(1.) The hereinbefore described art or method of electrical distribution and conversion, which consists in establishing in a closed electric current a current of alternate and equal positive and negative potential, producing by the influence of such current an inductive field of alternate polarity, and thereby inducing in translating devices situated in an independent closed circuit traversing such field a similar alternating secondary current of greater quantity and less potential than the originating or producing current."

I do not see any material difference between the claim which was refused to me in 1883, and that which is granted to Messrs. Gaulard and Gibbs in 1886. It is quite apparent that the examiner in 1886 had a clearer view of the function of an induction coil than was the case in 1883.

I may also mention that in my experiments at that time I made use of a continuous iron core for the induction coil.

Although I am quite willing to acknowledge the merit of those who have in the meantime brought this system into practical application, I do suppose that I am entitled to all those rights which are due to me on account of priority in invention.—Yours, &c., ALEXANDER BERNSTEIN.

The Bernstein Electric Lamp Company (Limited),
9A, Commercial-road, London, S.W., Nov. 20, 1886.

INCANDESCENT LAMP MANUFACTURE.

BY J. SWINBURNE.

Perhaps nothing so simple is so little understood as the incandescent lamp. It is merely a piece of carbon enclosed in a globe with the air pumped out; yet it costs 5s., without any obvious reason, and the cost of electric lighting is more than doubled by people not knowing how to run their lamps properly.

As no full account of the manufacture of incandescent lamps has yet appeared, it is hoped an attempt may be welcomed not only by those who are already engaged in lamp manufacture, but also by those whose success depends on their proper use, and by the large class who take an interest in a manufacture that involves so many branches of applied science.

It is the policy of incandescent lamp makers to keep their processes and modes of manufacture as secret as possible. At first this was, no doubt, very good policy on their part, but it is questionable if it does them much good now. The result of it is that each maker has to go through a number of tedious and very expensive experiments, which might have been saved. Moreover, the secret processes so jealously guarded are probably much the same in different factories, and the success of a lamp maker must soon depend, not on secret processes but on good business management, not only in making but in selling his lamps. The present high price of lamps is not due to labour in making but to superintendence, to waste through manufacture of bad lamps, which are or are not sold, and to bad business management and waste of money generally. In addition, large sums have often been paid for patents of doubtful value.

There is no exception in the case of incandescent lamp making; it has to go through the same vicissitudes as other branches of electric lighting. We blame the Electric Lighting Act, as it is a very convenient scapegoat, but the slow progress of electric lighting is mainly due to our own incapacity, not to legislation or to speculative companies. Electric lighting, as a new business, needed men who had technical knowledge as well as business capacity; and even now, after four or five years' work, an electrical engineer knows less about his work, in proportion to the position he holds, than most other professional men. This, of course, is unavoidable in a new industry. To begin with, electrical businesses had to be managed by men who were either scientific and unbusinesslike or businesslike and unscientific; much was done by people who knew nothing either of science or business. The result has been that what may be called electric light management has arisen, its most obvious features being great hurry with no speed, great expectations with no reason for them, and generally doing everything at night that should be done in the day. The industry is looking more promising

Digitized by Google

now, as electricians are gradually acquiring business habits, and business men see that it is necessary to be technical also.

Incandescent lamp making is the most purely scientific branch of electric lighting, and it has therefore suffered most from unbusinesslike management. It is probable that lamps will gradually fall in price during the next few years as lamp factories are better managed. These articles cannot, unfortunately, give any useful information on the subject of management; but it is hoped they may be found of technical value to lamp makers themselves. Of course every lamp maker thinks he, and he alone, knows how to make lamps; but though each manufacturer knows a great many things unknown to other people, he is also ignorant of many things known to almost everyone else. It will be the writer's endeavour, therefore, to give as full an account as possible of what he knows and of what he has found in his own experience. This cannot but tend to help lamp makers out of some technical difficulties, and to reduce lamp making to its proper level of a commercial manufacture with legitimate profits. Electric lighting may be said to be on a firm basis when people give up inventing and substitute designing; lamp making when success depends on well organised manufacture, not on patents or processes.

As the writer can only describe what has come within his own experience, it must be understood that when he writes about his own processes and apparatus, it is because he knows them best, not because they are in universal use or particularly good.

History.

It is unadvisable to write a history of the incandescent lamp here, for several reasons. In the first place, this is not an encyclopædia article; and, in the second place, the history of the incandescent lamp is to be found almost word for word in the numerous books on electric lighting published in England and on the Continent. One of the best accounts is in "Electric Illumination," by James Dredge. The idea of using a thin carbon in a vacuum for lighting is at least half a century old. About 1836 the question of lighting mines more safely seems to have occupied great attention in Belgium. It was then proposed to use carbon in a vacuum. It is very difficult to find out much about what was done in those early days, as papers of that date are not easily got. The earliest mention of incandescent lamps seems to be in the *Courier Belge* of 1836, quoted by Louyet in the *Comptes Rendus*, 1846, page 225; "*Nous voulons parler de l'incandescence de charbon produite dans le vide au moyen d'une pile voltaique.*" It appears that De Changy took the matter up soon after, and he seems to have worked both with platinum and carbon, but to have been more successful with platinum. It is difficult to find out much about De Changy's lamps. Most of the accounts of electric lights in those days are too vague and exaggerated to be of much use now. It seems, however, from a technical account that appeared in one of the French journals, that De Changy's lamp, as exhibited, was a platinum lamp. The next period of activity in electric lighting was between 1845 and 1855. Anyone interested in the history of lamps will find many accounts in the *Mechanics' Magazine* of that time. The electric light seems even then to have been a mere curiosity, useful for displays, or for astonishing fish, but the cost of primary batteries prevented its commercial use as an illuminant. Any further information can be got from the excellent article in "Electric Illumination" already mentioned. The incandescent lamp was not invented by anybody. It was a gradual growth, like the arc lamp; and immediately the dynamo became a commercial success, and the incandescent lamp was wanted, it was forthcoming. Those who have studied not only the arc lamp patents but the electrical patents generally of forty years ago must see that very little new has been brought out during the last six years; the only thing wanted to make both arc and incandescent lighting a success even then was a commercial demand for it. If credit is due to any one for the introduction of the incandescent lamp it is to Swan, Lane-Fox, and Stearn for doing the work, and to Edison for making a noise about it. There are, no doubt, many subordinates who have done good work, but whose names naturally do not come before the public; such, for instance, as Mr. F. Topham, Mr. Stearn's ingenious assistant. Incandescent lamp makers are also indirectly indebted to Mr. W. Crookes for his work on high vacua. It is probable that incandescent lamp makers, though they may be unable to tell scientific men much about very high vacua, may be able to show them how to make very much simpler and better pumps than those used in the laboratory; yet this is but a slight return to Sprengel, Geissler, and Crookes.

Preparation of the Carbon.

The first quality necessary to a carbon is that it should be durable at high temperatures in a vacuum; the second that it should be easy to make; and the third that it can be made of any size, surface, or resistance that may be required. The commonest cause of failure is not, as might be supposed, the first, but the third. People have often made a few lamps in the laboratory, and concluded that they have invented a lamp, and that there is nothing further to do but to make it in large quantities. The disappearance of the numerous lamps that have been brought out one after the other during the last few years is mainly due to the impossibility of making them wholesale. The inventor who has made a few dozen lamps with some new form of carbon, so far from having done his work, has only just begun it, and, as likely as not, has begun it wrong. He afterwards has to invent or design apparatus for manufacturing on a large scale with uniformity.

The different forms of carbon may be subdivded and treated separately. The various kinds commonly used may be classified as:—

Retort carbon, or carbon deposited from gaseous hydrocarbon by heat.

Vegetable carbon of organic structure, such as carbonised paper, bamboo, roots, scrubbing brush bristles, &c.

Amyloid, as used by Swan, Weston, and the Anglo-American Brush Corporation.

Animal, such as silk, catgut, &c,

Chemically deposited, as Smith's.

There are a few varieties not included in the above list, but they can be described separately.

BRITISH ASSOCIATION, 1886.

The following papers marked * were contributed to the late meeting of the British Association on various subjects connected with Electrolysis.

PROF. BOUTY ON ELECTROLYTIC CONDUCTIVITY.*

(*Concluded from page 35*).

In all these cases one may notice that *electrolytic reactions which go on for the most feeble currents absorb always less heat than those which occur with stronger currents.* This extension to mixtures of the beautiful law announced by Berthelot for the case of electrolysis of a single salt is confirmed by a study of particular cases. For instance, the following table sums up the author's observations on a mixture of $\frac{9}{10}$ by volume of a solution of Na_2SO_4, and $\frac{1}{10}$ of a solution of $CuSO_4$, both pure and saturated when cold. The polarisation of anode is so small as to be negligible; the polarisation of cathode is given for various intensities of current in ten-thousandths of an ampere per square centimetre.

Current Intensity.	Polarisation of Cathode in Volts.	
7	·042	Brilliant deposit of copper.
10	·044	
15	·045	
19	·051	
31	·068	
36	·100	
41	·162	
44·7	·298	
45·4	·859	Brown deposit.
77	1·366	
150	1·585	Abundant evolution of hydrogen

The brown deposit of oxide appears as soon as the polarisation exceeds ·28 volt. The polarisation increases first very

Digitized by Google

rapidly, then slowly, and its limit is very nearly the number (1·428 volt) which corresponds to the decomposition of Na_2SO_4 between copper electrodes. (It is slightly sophisticated by the extra resistance of gas bubbles then given off.) To sum up: First is decomposed $CuSO_4$, which theoretically consumes no energy (the electrodes being copper), then comes in the decomposition of acid water (·28 volt), finally that of sulphate of soda (1·424).

As for the conductivity of the mixture, it remains perfectly invariable in spite of the variability of the electrolytic reactions.

M. Bouty then quotes a saying of Wiedemann, that from a mixture of any of the following metals, Zn, Cd, Pt, Cu, Ag, Au, any metal which follows in the list is deposited to the exclusion of any which precedes. This is manifestly in accord with the above law, for the metals are in order of thermal equivalents. But the fact is only true for feeble currents. With strong currents a mixed deposit is obtained.

To sum up: *Liquids have, like metals, only one mode of conducting electricity. Also, they have, like metals, only one contact E.M.F. with an electrode of invariable composition.* But the result of electrolysis being to modify both electrode and liquid round it, their contact E.M.F. alters in a variable manner—whence polarisation.

SUR LA CONDUCTIBILITE ELECTRIQUE DES DISSOLUTIONS SALINES TRES ETENDUES.

By M. E. Bouty.* Abstract by Oliver Lodge.

I. *Historical.*

"The electric conductivity of salts dissolved in water varies with concentration in a manner extremely complex and differing for different salts. One possesses neither general law nor empirical formula, of however limited an application. One conceives *à priori* that this conductivity depends on the chemical nature of the salt, on the hydrates it can form, and on their stability; experience establishes also that it is not without relation to some physical properties of the solution, in particular its viscosity. But the separation of these circumstances has not yet been made. There seemed to me room first to simplify the problem by considering only solutions of identical physical properties. I have therefore chosen solutions so dilute that their density and viscosity are the same as pure water; their conductivity is yet relatively enormous, and can be measured easily by an electrometric method derived from that of M. Lippmann,"

In this method, as now applied, the tapping electrodes are zinc in sulphate of zinc, communication being established between the experimental fluid and the sulphate of zinc by a pair of capillary openings in the experimental tube. The difference of potential between these tapping electrodes is either measured by a Lippmann electrometer and compared against another difference taken at the ends of a known wire in the same circuit, chosen so as to be as nearly equal in resistance to the liquid as possible; or, what is plainly better, it is compensated by an auxiliary wire, and the electrometer brought to zero.

The author quotes Kohlrausch's views as expressed in his paper in Wiedemann's *Annalen*, VI., pp. 1, 51, 145, 210; but he objects to them as founded too much on extrapolation, the conclusions being stated for extremely dilute solutions, while those experimented with contained $\frac{1}{20}$th of their weight of salt. "So, although my results present a general agreement with those of M. Kohlrausch within the limits in which he has himself worked, I find myself led for their interpretation to conclusions absolutely different from that of the learned German professor."

II.—*Method of Measurement.*

The liquids to be compared are contained in two long vertical inverted U tubes, dipping with their open ends into two pairs of porous pots, each pair full of the same liquid as is in its tube. The four pots, and also the two main (zinc) electrodes, are contained in six separate glass vessels, all full of sulphate of zinc solution, connected up by short stout siphon tubes, as shown in Fig. 1. The tapping electrodes are zinc blocks, each in a Woulffe's bottle of sulphate of zinc, with a projecting and recurved full tube able to dip into any part of the liquid in the glass cells outside the porous pots, and so make connection (*see* Fig. 2).

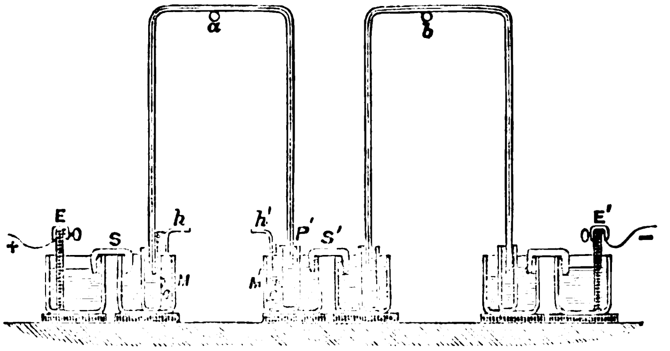

Fig. 1.

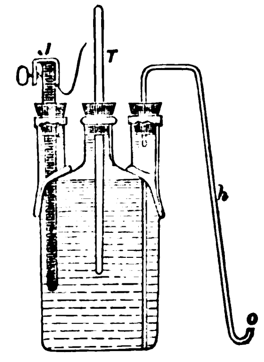

Fig. 2.

After taking readings for the two tubes filled with different liquids, they are both filled with the same liquid and fresh readings taken, so as to compensate for inequalities between the tubes.

III.—*Conductivity of very dilute Neutral-salt Solutions.*

"When one takes a solution of a neutral salt, already pretty dilute, and doubles the quantity of water it contains, the specific resistance is in general far from being doubled, as one would *à priori* expect; it is multiplied by a coefficient λ, smaller than two, which increases progressively with dilution and tends towards the limit 2, but only for excessive dilution. Here, for example, are some numbers furnished by sulphate of zinc:—

Initial concentration	*Ratio λ.	Initial concentration.	Ratio λ.
$\frac{1}{10}$	1 684	$\frac{1}{160}$	1·752
$\frac{1}{20}$	1·712	$\frac{1}{320}$	1·805
$\frac{1}{40}$	1·721	$\frac{1}{640}$	1 845
$\frac{1}{80}$	1 739	$\frac{1}{1280}$	1·953

Chloride of potassium gave in one experiment:—

Initial concentration.	Ratio λ.	Initial concentration.	Ratio λ.
$\frac{1}{30}$	1·921	$\frac{1}{240}$	1·933
$\frac{1}{60}$	1·943	$\frac{1}{480}$	1·958
$\frac{1}{120}$	1·931	$\frac{1}{960}$	1 945

* This "ratio λ" is plainly the same thing as Arrhenius' "exponent of dilution," only more simply introduced. I have shown in remarks on Arrhenius' memoir (first part) that the meaning of this "ratio λ," in so far as it is constant, is that conductivity varies as a power of the concentration, $k \propto m^r$ where $r = \log \lambda / \log 2$.

"Anhydrous salts behave in general like KCl, that is to say, the ratio λ is very near 2, even for moderate concentrations. Hydrated salts, on the other hand, are comparable to sulphate of zinc, and it is only for very great dilutions that their ratio λ approaches the value 2."

M. Bouty considers that at sufficient dilution the molecular conductivity of all salts is the same. For salts without water

Digitized by Google

of crystallisation a concentration of $\frac{1}{1000}$ or so may be permitted; but for hydrated salts it is necessary to go below these limits, a thing *which requires the possession of absolutely pure water*, and he is only able to show that they approach equality to the other class of salts when very attenuated. Two tables follow, showing ratios of resistances compared with ratios of concentration, first for anhydrous salts, and then for salts which crystallise with a definite amount of water, KCl being taken as the standard of reference.

(*To be continued.*)

SOCIETY OF TELEGRAPH-ENGINEERS—Nov. 25th.

Prof. HUGHES, F.R.S., President, in the chair.

After reading and confirming the minutes of the last meeting, Prof. G. FORBES continued the discussion on Mr. Kapp's paper, "On the Pre-Determination of the Characteristics of Dynamos," read at the meeting held on November 12th. Prof. Forbes, in the first place, referred to the work of previous writers, and particularly that of Frölich as the initiator of this subject; also to Prof. Rucker; and especially to the paper of the Bros. Hopkinson, read before the Royal Society. With regard to Mr. Kapp's paper, he objected most emphatically to the nomenclature and notation employed as leading to a great waste of brain power, and rendering the argument much more difficult to follow except to those who had plenty of time to spare. For himself, owing to Mr. Kapp adopting such mixed notation, he had been unable to work out some parts of the paper, and for the same reason he imagined that several of the conclusions were erroneous, although by a happy selection of constants the curve ultimately obtained was practically that required. Owing to Mr. Kapp's paper, read last year before the Institution of Civil Engineers, many students had probably turned their attention to the subject, which may shortly be stated as the ratio of waste to useful lines of force in the dynamo. Prof. Forbes went on to describe his own work n this direction, and pointed out that waste lines of force or leakage was calculable, and that he had calculated such lines by adopting three formulæ, or lemmas, one or other of which was applicable to each case of leakage. He took the first source of leakage as between the ends of the poles; the second source across the limbs of the field magnets: this source he divided into (α) direct leakage across; (β) leakage from the sides of the limbs: third source, leakage from the sides of the pole-pieces; and fourth source, from the backs of poles to ends of yoke. The most important portion practically of Prof. Forbes' criticism was at the conclusion, when he took exception to the idea that there must of necessity be waste lines of force in dynamos. He did not see why those waste lines should exist to any appreciable extent, and suggested for the consideration of practical men that the present system of winding was wrong. It is not the field-magnets that we want to magnetise, but the armature; then why not magnetise the armature directly by winding the copper so as to directly, and not indirectly, magnetise it? Prof. Forbes illustrated his suggestion by means of a diagram, and said that although difficulties might arise and the winding be in the way of the commutator, the difficulties of such winding ought not to be insuperable.

Dr. HOPKINSON said that during the discussion which had already taken place, much time had been devoted to the analogy of electric conductors with the subject dealt with by Mr. Kapp. For his part, he thought it better to set aside analogies, and examine the ascertainable facts. We had, it is true, a convenient law in relation to electrical conduction; but we know perfectly well it does not hold good for iron. Magnetisation is a function of exciting power, and as such we had better treat it rather than trouble to find its analogy with conductivity. He agreed with Prof. Forbes in his objections to the system of measurement adopted by Mr. Kapp, and in the expression of a desire that he would adopt the C.-G.-S. system. Turning to the subject of the magnetic field, Dr. Hopkinson stated that his brother and he had not attempted to calculate it in the manner suggested by Prof. Forbes. Still it was remarkable that that gentleman should have arrived at results so close to their own by a method totally different. Judged by his, Dr. Hopkinson's, experience, some of the figures said to have been obtained by Mr. Kapp were startlingly high; but he could not presume to question them further than that. He also concurred with Prof. Forbes in recommending the institution of careful experiments to be made into the magnetisation of iron, some of which he indicated. He concluded by paying a high compliment to Mr. Kapp, who had independently, and by his own unaided efforts, obtained results which were extremely valuable.

Dr. FLEMING said that it was essential to recognise that no algebraical formula could fully express the function of magnetisation. At the same time it was interesting to take Frölich's expression and compare it with the results obtained by Mr. Shelford Bidwell, when employing very high magnetising forces. Fröllich's formuia might be interpreted to mean that the reciprocal of the susceptibility of the iron to magnetisation is a linear function of the magnetising force. Now, Mr. Bidwell's curves distinctly showed this linear relation for magnetising forces between 10 and 600 C.G.S. units. But below 10 units the curve deviates very considerably from the straight line.

After a few words from Mr. SIDNEY F. WALKER, Prof. S. P. THOMPSON showed that the true characteristic of the dynamo might be drawn from the "characteristic of magnetisation," as determined by the methods of Kapp and Hopkinson. As this cannot be made intelligible without the aid of a diagram, we are unable to give it in this issue.

After Prof. THOMPSON's remarks, the President announced that a special meeting of the Society would be held on Thursday next, when the discussion will be concluded.

DYNAMO-ELECTRIC MACHINERY.

BY J. HOPKINSON, M.A., D.Sc., F.R.S., AND E. HOPKINSON, M.A., D.Sc.

(*Continued from page 43.*)

Experiment to determine ν.

Around the middle of one of the magnet limbs a single coil of wire was taken, forming one complete convolution, and its ends connected to a Thomson's mirror galvanometer rendered fairly ballistic. If the circuit of the field-magnets, while the exciting current is passing, be suddenly short-circuited, the elongation of the galvanometer is a measure of the total induction within the core of the limbs, neglecting the residual magnetisation. If the short circuit be suddenly removed, so that the current again passes round the field-magnets, the elongation of the galvanometer will be equal in magnitude and opposite in direction.

The readings taken were:—

Zero..........................	71	left.
Deflection	332	,, magnets made.
,, ...	196	right; magnets short-circuited.
Hence, deflection to right =	267	
,, left =	261	
Mean deflection =	264	

To determine the induction through the armature, the leads to the ballistic galvanometer were soldered to consecutive bars of the commutator, connected to that convolution of the armature which lay in the plane of commutation.

The readings taken were:—

Zero..........................	23	left.
Deflection	223	,, magnets made.
,, ...	176	} right; magnets short-circuited.
,, ...	178	}
Hence, deflection to right and left .... =	200	

It thus appears that out of 264 lines of force passing through the cores of the magnet limbs at their centre, 200 go through the core of the armature, whence ν equals 1·32. The magnetising current round the fields during these experiments was 5·6 amperes.

Experiments on Waste Field not passing through Armature.

As in the determination of ν a single convolution was taken around the middle of one of the limbs, and connected to the ballistic galvanometer, the deflections, when a current of 5·6 amperes was suddenly passed through the field or short-circuited, were:—

Zero..........................	34	left.
Deflection	148	,, magnets made.
,, ...	82	right; magnets short-circuited.
Hence, deflection to right =	116	
,, left =	114	
Mean deflection =	115	

I. Four convolutions were then wound round the zinc plate and the cast-iron bed in a vertical plane, passing through the axis of the armature; and the deflections noted:—

Zero..........................	15	left.
Deflection	61	,, magnets short circuited.
,, ...	40	right; magnets made.
Zero..........................	11	left.
Deflection	64	,, magnets short-circuited.
,, ...	36	right; magnets made.
Hence, deflection to right =	55	
,, left =	46	
and deflection to right =	47	
,, left =	53	

in the two observations respectively, given a mean = 50·25; or, reducing to one convolution, = 12·6.

II. A square wooden frame, 38cms. × 38cms., on which were wound ten convolutions, was then inserted between the magnet limbs, with one side resting on the armature, and an adjacent side projecting 5cms. beyond the coils on the limbs, or about 7·6cms. beyond the cores of the limbs. The deflections were:—

Zero	34 left.
Deflection	98 ,, magnets made.
,, ...	22 right; magnets short-circuited.
,, ...	21 ,, ,, ,,
,, ...	81 left; magnets made.
Hence, deflection to right =	56
,, left =	64
and ,, right =	55
,, left =	47

in the two observations respectively, giving a mean =55; or, reducing to one convolution, =5·5.

III. The same frame was raised a height of 6·35 cms. above the armature in a vertical plane. The deflections were :—

Zero	21 left.
Deflection	98 ,, magnets made.
Zero	35 left.
Deflection	8 right; magnets short-circuited.
Hence, deflection to left =	50
,, right =	43
and mean deflection =	46 5
or, reducing to one convolution =	4 6

IV. The same frame was again lowered on the armature and pushed inwards so as to lie symmetrically within the space between the limbs. The deflections were :—

Zero	32 right.
Deflection	112 ,, magnets made.
,, ...	48 left; magnets short circuited.

giving a mean of 80; or, reducing to one convolution, =8·0.

Let G represent the leakage through a vertical area bounded by the armature, and a line 7·6 cms. above the armature, and of the same width as the pole-pieces; let R be the remainder of the leakage between the limbs; then II. and III. give

$$\frac{2}{3}G+\frac{2}{3}R=5{\cdot}5 \quad \frac{2}{3}R=4{\cdot}6$$

whence $G=1{\cdot}35, \quad R=6{\cdot}9.$

Again IV. gives $\frac{5}{6}(G+R)=8{\cdot}0$

therefore $G+R=9{\cdot}6,$

which shows an agreement as near as might be expected, considering the rough nature of the experiment, and that the leakage is assumed uniform over the areas considered.

We take $G=1{\cdot}6 \quad R=8{\cdot}0$

Reducing these losses to percentages we have

$G=\frac{1{\cdot}6}{115}$	= 1·4	per cent.
$R=\frac{8{\cdot}0}{115}$	= 7·0	,,
And from I. the leakage through the zinc plate and iron base	= 10·3	,,
Hence the two gaps account for	2 8	,,
The zinc plate and iron base account for	10·3	,,
And the area between the limbs	7·0	,,
Making a total loss accounted for	20·1	,,
Out of an observed loss of	24·24	,,

The leakage through the shaft and from pole-piece to yoke, and one pole-piece to the other by exterior lines, will account for the remainder.

Effect of the Current in the Armature.

The currents in the fixed coils around the magnets are not the only magnetising forces applied in a dynamo machine; the currents in the moving coils of the armature have also their effect on the resultant field. There are in general two independent variables in a dynamo machine, the current around the magnets and the current in the armature, and the relation of E.M.F. to currents is fully represented by a surface. In well-constructed machines the effect of the latter is reduced to a minimum, but it can be by no means neglected. When a section of the armature coils is commutated it must inevitably be momentarily short circuited, and if at the time of commutation the field in which the section is moving is other than feeble, a considerable current will arise in that section accompanied by waste of power and destructive sparking. It may be well at once to give an idea of the possible magnitude of such effects. In the machine already described the mean E.M.F. in a section of the armature at a certain speed may be taken as 6 volts, its resistance 0·000995 ohm. Setting aside, then, for the moment questions of self-induction, if a section were commutated at a time when it was in a field of one-tenth part of the mean intensity of the whole field there would arise in that section, whilst short-circuited by the collecting brush, a current of 600 amperes, four times the current when the section is doing its normal work. The ideal adjustment of the collecting brushes is such that during the time they short-circuit the sections of the armature the magnetic forces shall just suffice to stop the current in the section, and to reverse it to the same current in the opposite direction.

Suppose the commutation occurs at an angle λ in advance of the symmetrical position between the fields, and that the total current through the armature be C, reckoned positive in the direction of the resultant E.M.F. of the machine, *i.e.*, positive when the machine is used as a generator of electricity. Taking any closed line through magnets and armature, symmetrically drawn as A B C D E F A (Fig. 4), it is obvious that the line integral of magnetic force is diminished by the current in the armature included between angle λ in front and angle λ behind the plane of symmetry. If m be the number of convolutions of the armature, the value of this magnetising force is $4\pi C\frac{m}{2}\frac{2\lambda}{\pi}=4\lambda mC$ opposed to the magnetising force of the fixed coils on the magnets. Thus, if we know the lead of the brushes and the current in the armature we are at once in a position to calculate the effect on the electromotive force of the machine. A further effect of the current in the armature is a material disturbance in the distribution of the induction over the bored face of the pole-piece; the force along B C (Fig. 4) is by no means equal to that along D E. Draw the closed curve B C G H B, the line integral along C G and H B is negligible. Hence the difference between force H G and B C is equal to $4\pi C\frac{m}{2}\frac{\kappa}{\pi}=2\kappa mC$ where κ is the angle C O G. This disturbance

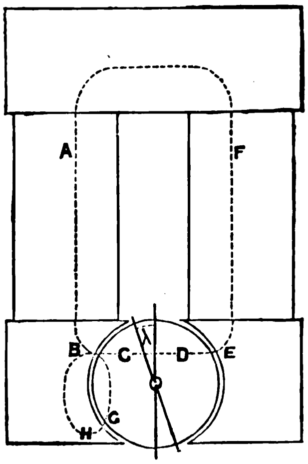

FIG. 4.

has no material effect upon the performance of the machine. But the current in the armature also distorts the arrangement of the comparatively weak field in the gap between the pole-pieces, displacing the point of zero field in the direction of rotation in a generator and opposite to the direction of rotation in a motor; and it is due to this that the non-sparking point for the brushes is displaced. A satisfactory mathematical analysis of the displacement of the field in the gap between the pole-pieces by the current in the armature would be more troublesome than *à priori* analysis of the distribution of field in this space when the magnet current is the only magnetising force. Owing to the fact that the armature is divided into a finite number of sections, there is a rapid diminution of the displacement of the field during the time that a section is being commutated, the diminution being recovered whilst the brush is in contact with only one bar of the commutator. The field thus oscillates slightly, owing to the disturbance caused by reversing the direction of the current in the successive sections of the armature. The number of oscillations in a Gramme armature or in a Siemens armature with an even number of sections will be ρm, where ρ is the number of revolutions per second, but in a Siemens armature with an odd number of sections it will be $2\rho m$.* This oscillation of the field is only another way of expressing the effect of the self-induction of the section, but it must be remembered that if the self-induction, multiplied by change of current, is expressed as a change in the field we must omit self-induction as a separate term in our electrical equations. The precise lead to be given to the brushes in order to avoid sparking in any given case depends on many circumstances—the form and extent of the pole-pieces, the number of sections in the armature, and the duration of the short circuit which the brushes cause in any section of the armature. The adjustment of the position of the collecting brushes is generally made by hand at the discretion of the attendant, and is in some cases fixed once for all to suit an average condition of the machine. We shall therefore treat λ the lead as an independent variable, controlled by the attendant.

Let I be total induction through the armature, I + I′ total induction through the magnets, I′ being the waste field. Let C be current in armature, c in the magnets. Let gI′ be the line integral of magnetic force from a point on one pole-piece to a point on the other, the line being drawn external to the armature, g will be approximately constant. Omitting as comparatively unimportant the magnetising force in the pole-pieces and iron core of the armature, we have the following equations :—

$$4\lambda mC+2l_2\frac{I}{A_2}-gI'=0$$

$$4\lambda mC+2l_2\frac{I}{A_2}+l_3f\left(\frac{I+I'}{A_3}\right)=4\pi nc.$$

* Added Aug. 17.—Armatures with an odd number of convolutions are open to one theoretical objection, which would be a practical one if the number of convolutions were very small. The $2m+1$ convolutions constitute in themselves a closed circuit, having a resistance four times the mean actual resistance of the armature measured between the collecting brushes. When any one convolution is exactly in the middle of the field the E.M.F. of the other $2m$ convolutions exactly balance, so that there is upon the closed circuit an E.M.F. due to the single convolution somewhat in excess of $\frac{1}{m}$th part of the actual E.M.F. of the machine. Thus there will be an alternating E.M.F. around the closed circuit of the armature capable of causing a considerable waste of power. This waste is materially checked by the self-induction of the circuit.

Digitized by Google

When C=O we observed $I = \frac{1}{\nu - 1} I'$

whence $g = \frac{1}{\nu - 1} \frac{2 l_2}{A_2}$

eliminating I′

$$\frac{2 l_2}{\nu A_2}\left(\nu I + 4 \lambda m C \frac{A_2}{2 l_2} (\nu - 1)\right) + l_3 f \left\{\frac{\nu I + 4 \lambda m C . \frac{A_2}{2 l_2}(\nu - 1)}{A_3}\right\}$$

$$= 4 \pi n c + 4 \lambda m C \frac{\nu - 1}{\nu} - 4 \lambda m C = 4 \pi n c - 4 \lambda m C \frac{1}{\nu}.$$

The characteristic curve when C=O being $I = F(4 \pi n c)$ we may write the above as the equation of the characteristic surface thus

$$I + \frac{\nu - 1}{\nu} 4 \lambda m C \frac{A_2}{2 l_2} = F\left(4 \pi n c - \frac{4 \lambda m C}{\nu}\right).$$

In applying this equation it must not be forgotten that the E.M.F. of the machine cannot be determined from I unless the commutation occurs at such a time that the coil being commutated embraces all, or nearly all, the lines of induction in the armature.

This equation enables the characteristic surface to be constructed from the characteristic curve. Let $OL = 4\pi nc$, $LM = 4m\lambda C$. draw M K so that $\frac{KL}{LM} = \frac{1}{\nu}$, through K draw ordinate K R meeting characteristic curve in R,

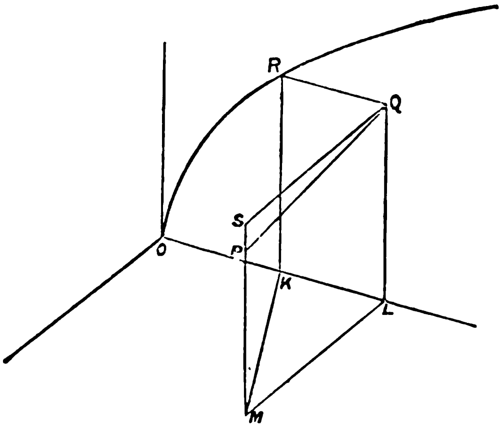

FIG. 5.

draw R Q parallel to O L meeting ordinate Q L in Q, draw Q S parallel to L M; draw Q P so that $\frac{PS}{SQ} = \frac{\nu - 1}{\nu} \cdot \frac{A_2}{2 l_2}$. Then P is a point on the characteristic surface.

(To be continued.)

LEGAL INTELLIGENCE.

The Direct Spanish Telegraph Company (Limited) *v.* Bannatyne.

On the resumption of the hearing of this case (which has been fully reported in recent issues of *The Electrician*) on Monday last, Mr. Rigby briefly recapitulated his arguments to show cause why the injunction granted by Vice-Chancellor Bacon should be overruled, concluding by reading the judgment delivered by the Vice-Chancellor.

Mr. P. BEALE pointed out that the question to determine was what was the real nature of the contract entered into with the preference shareholders by the light of the Act of 1867, and the special resolution passed in 1874, contending that there was nothing therein to show that, upon a reduction of capital, which the Company by that Act and their Articles were empowered to effect, the preference shareholders were entitled to any advantage over the ordinary shareholders. In this case there was no pretence that on a distribution of the assets or winding up of the Company the preference shareholders would get any priority. It was suggested that to refuse the injunction would be to establish a dangerous precedent, and enable directors to break the bargain they entered into with pereference shareholders. But what the Company proposed to do was simply to reduce the amount of the nominal capital unrepresented by assets, which was exactly the same thing as if by the Act of 1867 they reduced it by giving the holders half their money back. It was difficult to see, under Articles 7, 9, and 10, how capital could possibly be reduced if it were not to be reduced so as to put all the shareholders on an equality. The suggestion on the other side was to look at the position of the preference shareholders as if the Company were to grant them an annuity, but their lordships would agree that the Articles were not to be read in that way. In the affairs of an ordinary partnership would it not be perfectly right for the majority to be able to say, "We will deal with this by writing off the capital," just as they might say, "We don't want to use so much capital, we will return it?" There was a fair analogy between the company and an ordinary partnership. The reduction of capital was in reality very much like a winding up. They were only doing that which any prudent man of business would do when he lost his capital.

Mr. MARTEN, Q.C., said that, however much his learned friends might disguise it, the real effect of the resolution which had been passed would be to take money out of the pockets of the preference shareholders and put it into those of the ordinary shareholders. He contended that it was *ultra vires* on the part of the Company to pass any such resolution. As he understood it there could be no difficulty in the Court's determining the broad question whether or not capital could be reduced in the way proposed. That had been the question argued by Mr. Rigby and Mr. Beale: not whether it was competent for the Company to pass a resolution which contemplated the reduction of capital, by which the preference shareholders would be deprived of their dividends; and he asked their lordships to determine that question. The real question turned upon the construction of the three resolutions of 1874, and upon the construction of the circular which followed it. Those resolutions said: "That for effecting this purchase, and for other purposes of the Company, the Directors be and they are hereby authorised to increase the capital of the Company by the issue of 6,000 new shares of £10 each to be paid in full on allotment." "That such new shares should be entitled to a fixed preferential dividend of 10 per cent. per annum, and that if in any year the net profits of the Company should not be sufficient to pay the whole of such preferential dividend for that year, the balance should be paid (but without interest) out of the profits of the next year, and if need be of succeeding years." He submitted that that meant that the preference shareholders were always entitled to a fixed dividend of 10 per cent. on the capital they paid up, not with respect to the amount for the time being. The true construction of the bargain he thought had been put upon the documents by the learned Vice-Chancellor, who said that that was a bargain made once for all, and it would be doing violence to all ordinary understanding of language otherwise to construe it. Since the Act of 1877 was passed the other side said: "We can nullify that contract and reduce the capital, so that the money that was appropriated for your dividend will be put into the pockets of the ordinary shareholders." As the Vice-Chancellor pointed out, that would be a correct view of that which would happen if their lordships were to set aside the decision arrived at, and to introduce new elements never contemplated when the bargain was made. It was said that Section 10 of the original Articles authorised the reduction of capital, and that the special bargain should be subject to that.

Lord Justice COTTON pointed out that the Article referred to also said that power was granted to "alter the amount and denomination of its shares."

Mr. MARTEN contended that they could not alter the nominal amount of the shares of the bargain. No amount of alteration of the shares could alter the real bargain that the preference shareholders were to have a fixed dividend of 10 per cent. on their paid-up capital. They were entitled to an annuity of £6,000 a year, and the result of the resolution would be to take £3,000 of that away. Mr. Beale compared the passing of the resolution to the action of the majority in an ordinary partnership. The answer to that was simply that it was contrary to the original bargain to make use of the power they had to reduce capital for the purpose of benefiting one class of shareholders at the expense of the other. Put into plain English, the scheme came to this, that they were going to take £3,000 from the preference shareholders and hand it over to the ordinary shareholders. It would be a startling thing if the millions that had been invested in this country in preference shares could be treated in that way. and he submitted that the powers contained in Article 10, and the statutory power to reduce capital did not interfere with the bargain.

Mr. H. B. HOWARD followed, and remarked that there was nothing improper or *ultra vires* in the Company reducing their capital in the way they wished to do. There was no objection to that course so long as the preference shareholders received their £6,000 a year.

The Court then adjourned till Tuesday morning.

JUDGMENT.

On resuming, on Tuesday morning, Lord Justice COTTON said: This is an appeal from Vice-Chancellor Bacon, which raises a very important question. This Company, who are the defendants in this action, was formed in the year 1872 or 1873, and it had a capital, with power to add to that capital, and with power to give preference to any shares that might be created. Articles 7, 9, and 10 are the Articles which are most important. In 1874 resolutions were passed to increase the capital by 6,000 new shares, and those shares were to have a preference as regards dividend, but no preference as regards capital. They lost one of their cables, which, of course, was a loss of a considerable part of that which represented their capital. Resolutions were passed that they should reduce their capital by striking off half the nominal amount of each of the shares, both ordinary shares and preference shares, and then the injunction was granted by Vice-Chancellor Bacon, on the action of one of the shareholders who held preference shares as well as ordinary shares, and this is an appeal as against that injunction, the appeal, of course, being the appeal of the Company. Now, Articles 7, 9, and 10, to which I have referred, are these:—Article 7 is, "The Directors may, with the previous sanction of a special resolution of the Company, increase its capital by the issue of new shares to such an aggregate amount, with such preferential right to dividend and such priority in the distribution of assets, or subject to such postponement of dividends, or in the distribution of assets, as shall in such special resolution be provided." Article 9 is, "All capital raised by the creation of new shares shall be considered as part of the original capital, and shall be subject to the same provisions in all respects as if it had been part of the original capital, except so far as these Articles or the resolution authorising the raising thereof may otherwise direct." Section 10 is,

Digitized by Google

"The Company may also, by special resolution, from time to time, reduce its capital and also alter the amount and denomination of its shares." Well, the Act of 1867 was then, of course, in operation, and this Article 10 must be regarded with reference to that Act; of course, it could not have been effectually done but for that Act, but we have got that in the Articles. In my opinion that is important to be considered in dealing with the question as to what was the bargain under which the preference shareholders took their shares. I think I need not read the resolution for diminishing their capital that was passed on the 30th September, 1886, after the Act of 1877 came into operation. Previous to the Act of 1877 there would be no doubt that what there was proposed to be done was sanctioned by Parliament, but, of course, one cannot look to that Act of 1877 for the purpose of considering what the bargain was under which the preference shareholders came in. On what ground is the injunction asked for? I need hardly refer to the Act of 1867, where there is in general terms power given to reduce the capital, preference capital being a thing then well known and very usual in companies under the Act of 1862, as well as in companies under the Companies Clauses Act; but that was general. How is it contended that the action of the Directors and Company under that Act, and also now under the Act of 1877, is *ultra vires*, beyond their power, and that it is to be restrained? Now, as regards its being beyond their power, I, myself, do not entertain any doubt that under those Acts it is authorised; but the question still remains as to whether it is contrary to the bargain which was made between the Directors and the Company and those who took their preference shares, and one must consider that question. It was contended, I think, though that probably was partly abandoned, that the existence of these preference shares showed that there was a separate contract that there could be no reduction of capital. That, probably, was afterwards abandoned, but still one must deal with the question. In my opinion that contention cannot prevail. The Act of 1867, as I say, deals generally with power to reduce capital, and the very Articles of Association in this case provide that the preference shares when formed shall be part of the capital. If there was a winding up, the capital being lost, wholly, or in part, the preference shareholders and the ordinary shareholders must bear the loss ratably between them, because, as I say, these shares were constituted without any preference as regards capital, though they had a preference as regards dividend. Then, if that is so, and there is a loss of capital, in consequence of which there is a reduction made in the capital of the Company by dividing the shares, by reducing the denomination of the shares, that must be borne not only by the ordinary shareholders but also by the preference shareholders, and it was really hardly contended ultimately that there could be no reduction of capital, in consequence of the existence of preference shareholders having a preference in dividend only, and not a preference as regards capital, which was to be returned or which was lost, and in consequence of that loss there was a reduction of the capital and a reduction of the amount of the shares. But then it is said that the contract in this case would be broken unless the preference shareholders still had the same amount of dividend as they now have. It was put in this way. It was said here, these shares (I will read the resolution) are constituted with a preferential dividend, being fully paid up, of 10 per cent. That is equal to £1 per share, and we must look at the matter as if there had been a contract to give them perpetually as long as profits could be in any way obtained, so as to provide them with an annuity of £6,000 a year. That was the argument, and that by what you are doing, although you might reduce the capital, yet you ought not to cut off any portion of that annuity of £6,000 a year. You may reduce the capital, if you in your resolution to reduce the capital provide that that annuity of £6,000 a year shall still be paid to the preference shareholders, though their shares are reduced from £10 shares to £5 shares. That, I think, was the argument. Now let us see what the bargain was. I may say that, for my own part, if there was a bargain which will be broken by the reduction of capital, I think that the plaintiffs, and the shareholders in the same position, would have a case not to destroy the powers of the Act of Parliament, but to prevent those who had contracted with them from breaking their contract and of applying the powers of the Act to prevent them using the powers given to them by the Act. They are powers given, and not duties imposed on the Company or its Directors. Here, what contract is there, and how would that be broken by what is proposed to be done? Now, it is this, that the Directors are authorised to purchase for the Company a new submarine cable. "That for effecting this purpose and for other purposes of the Company, the Directors be and they are hereby authorised to increase the capital of the Company by the issue of 6,000 new shares of £10 each to be paid in full on allotment. That such new shares shall be entitled to a fixed preferential dividend of 10 per cent. per annum," and then there is the right, if the profits in any year shall not be sufficient, to have recourse indefinitely to the profits in the following year. Well, now, it was practically not contended, and in my opinion it could not be successfully contended, that the second resolution providing that there shall be a new issue of new shares of £10 each, the contract therein contained would be broken by applying under the Act to reduce the shares, all of them, ordinary and special, from £10 shares to £5 shares. Is there any contract in the third resolution as to dividend which prevents this being done, or prevents it being done while the dividend which will be paid to the preference shareholders is 10 per cent. only on what will then be the amount of their shares? "Such new shares shall be entitled to a fixed preferential dividend of 10 per cent. per annum." It is very true that the 10 per cent. there will be 10 per cent. on what was actually paid on the shares; but, in my opinion, it is not £1 on the shares, not a dividend for ever of £1 on each share, or an annuity of £6,000 a year, but it is 10 per cent., and if for any reason the amount of the shares is reduced from £10 to £5—which will be the result if these resolutions for the reduction of capital are carried into effect—then the bargain, in my opinion, will be performed by giving the holders of those preference shares 10 per cent. on the then amount of their capital in the Company. They will, of course, have only half what they previously had, because their shares, or half their shares by reduction of capital, are reduced from £10 to £5 a share, and one must take into consideration this—that at the time when this bargain was made there was this special provision in the Articles, that the Company might from time to time reduce its capital and also alter the amount and denomination of its shares. In my opinion what has happened was not contemplated. I do not say that it was, because the loss of the cable which caused the loss of half their capital was a matter which they would not contemplate, but still those who make a bargain where the Articles have that provision and are in the terms which I have read, ought to know, if they considered the matter at all, that, although they took the shares of £10 with a contract that there should be 10 per cent., which so long as the shares were £10 would give them the £1 a share, that there was in the clause in the Articles a contemplation of its being necessary to reduce the capital, and therefore they ought to take that into consideration; and in my opinion also they ought to be considered as knowing and taking into consideration the provisions of the Act which then existed of 1867, which provided that a company limited by shares may, by special resolution, modify the conditions contained in their Memorandum of Association, and authorised so to do by its regulations as originally framed or as altered by special resolution as to reduce its capital. That, I say, is in general terms, which would apply not only to original non-preferential capital, but to any preferential capital; and, as regards the bargain here, Article 10 is clear to my mind that that would apply to any preferential shares which might be created, especially having regard to the previous Articles, which said they were to be considered as part of the original capital. It was contended that although there is now an Act of 1877, which renders it possible effectually to do that which the resolution proposes to do at the time when this bargain was made, there was only the Act of 1867 in operation, and that Act, it was said, had been decided not to enable this to be done, and that for that reason the Act of 1877 was passed. Now, of course, the law alters and changes rather, but so far as we can consider what was in the minds of the parties at the very time when this bargain was made by the issue of the new shares there was a decision that this could be done under the Act of 1867, and although the late Master of the Rolls, in the case of the Ebbw Vale Company, in January, 1877, did decide that it could not be done, yet the Act of 1877 did not recognise that as law, but merely, in order to remove doubts and difficulties, was passed as a declaratory Act, declaring what was the effect and operation of the Act of 1867. So far as anything in the minds of the parties was concerned, the decision as to the law as it stood in 1874 was that which alone they could regard, but I am by no means prepared to say that I think the view of the late Master of the Rolls, expressed in 1877, was the correct view. I should think that the Act of 1867 was quite wide enough of itself to enable what has now been done to be done; but as regards the understanding of the parties, in my opinion there must be looked to what was then declared to be law by, I think, Vice-Chancellor Bacon, and not to the doubt which was subsequently raised by the decision of the late Master of the Rolls on the true construction of this contract. In my opinion there is no breach of that contract by what the Directors propose to do, by diminishig the capital and allowing the dividend to still remain 10 per cent. on the then reduced amount of the shares. Now, I have entered into that for the purpose really of dealing with the questions which are in contest between the parties here, but if we could not hold that the mere reduction of capital and application to the Court to sanction that—one of the judges of the Chancery Division to sanction that—that would not be a breach of any contract, and in my opinion we could not really regard what the Directors propose to do in consequence of that reduction. If they were merely doing this, not honestly for the purpose of reducing capital, but for some indirect other purpose, that might be a question raised; but that is not raised, and though I think myself that the judge when he has to consider, under the provisions of the Acts of 1867 and 1877, whether he shall make an order sanctioning, is only required by the Act of 1867 to be satisfied that the creditors are duly protected, yet when he is satisfied of that, he only gets power to authorise the scheme which is proposed. The words are:—"He may make an order, confirming the reduction on such terms, and subject to such conditions as he deems fit." That leaves a discretion in him, and in my opinion, although it is not necessary to decide that point, I think the action fails, and the judge, when the matter is brought before him, if he sees it bears hardly on those who do not consent, may take that into consideration, and I think one ought not to sanction a scheme simply because the creditors, who must be looked to, are dealt with properly, and have no ground of complaint. I thought it right to express my opinion on that point, as the matter has come before us, and we have had the questions argued. I cannot think that when the words of the Act, "That he may make an order, subject to such terms and conditions as he thinks fit," render it obligatory on him to make an order confirming the scheme if those things without which he cannot act only had been done. In my opinion this action fails, and the injunction ought to be discharged. I should mention that the parties have agreed that this should be taken as disposing of every matter, without prejudice to their right of appeal; therefore the injunction will be discharged, and I suppose the action will be dismissed with costs.

Lord Justice FRY: In the year 1867 there was passed a statute which we have had to consider in this proceeding. That provided that any company limited by shares might by special resolution so far modify the conditions of its Memorandum of Association, and receive certain authority to reduce its capital. The words of that sub-section are very general, and it refers to any company limited by shares. It appears to me that, bearing in mind the fact that at the time that Act was passed the

Digitized by Google

existence of the preference capital was a common and well known fact, and that the legislature must be taken to be dealing with the full knowledge of that fact, it is impossible to contend that a company limited by shares does not include a company some of whose capital may be preferential capital, and, in fact, I do not think that the contrary was argued in this case. Now, that being the enactment of 1867, what we learn from the authorities is this, that the course of practice under it enabled companies to diminish and reduce capital, although paid up. Such an order was made by the Vice-Chancellor Mallins in the case of the Muntz Metal Company in July, 1870, and a similar order was made by Vice-Chancellor Bacon in the matter of the Financial Company in January, 1871. As far as our attention has been drawn to the authorities, and as far as they are known to us—at any rate known to me—no doubt had been cast on the power of the Court to sanction the reduction of capital, although paid up before January, 1877. That being the state of the law as declared by Act of Parliament and by the authorities, this Company was registered in 1872. By the series of Articles of Association which deals with the increase and reduction of capital, the Company was authorised to increase its capital—to give a preferential right to these shares if the Company thought fit. It was declared that the new capital so raised should be considered as part of the original capital, and there was further an express power given to reduce the capital of this Company. Now, pausing upon these Articles of Association, it appears to me to be plain that the intention of it was to authorise the creation and the reduction of preferential capital. Then we next come to the special resolutions passed in July, 1874, when the state of the law and practice under the Act of 1867 remained as I have already stated. By the resolutions then passed preferential capital was created; each share consisting of £10 was to be paid up fully on allotment, and the third resolution provided that the new shares should be entitled to a fixed preferential dividend of 10 per cent. per annum. Now, the question which has been argued before us is this, whether or no those special resolutions do create a contract which excludes this Company from the right of applying to reduce its preferential paid-up capital. Now, having regard to the state of the law, and having, especially, regard to the Articles of Association with which these special resolutions must be read, it appears to me to be reasonably plain that the intention of the parties was that the preferential capital so to be created would fall under the operation of the 10th Article, and be capable of reduction. It seems to me to be reasonably plain that if it was the intention of the contracting parties to exclude that, the resolutions would have been very differently framed to what they are. They would be in such undoubted terms as to exclude that power. The language appears to me entirely opposed to any such contention as that which was addressed to us by the respondents because the right is a right to a fixed preferential dividend of 10 per cent. per annum. But on what? Obviously, it seems to me, on the amount of the shares, those shares being, as I have already stated, according to my view of the true construction of the instruments, subject to the power of reduction. The contention of Mr. Marten was, it seems to me, a rather extraordinary one. He did not deny the right of the Company to reduce the preferential capital, but he maintained if the preferential capital were reduced the preferential dividend must be proportionately increased, so that that should be a consonant. That would violate the very words of the resolution, which fixes the preferential dividend not at a given sum, but at a certain percentage on some other sum which is not expressed in the resolution. That is an entirely untenable contention. I think, therefore the true view of the bargain between the parties was this, that the preferential capital was created subject to the right of reduction which was expressly provided for in the Articles of Association. There are no words, no indication whatever, in those resolutions to exclude the power so expressly given to the Company. It appears to me not necessary to say any more on that. That determines one of the necessary propositions on the part of the plaintiffs adversely to them. Various other questions have been referred to, and more or less discussed, during the argument. I am far from expressing any difference of opinion in the view which Lord Justice Cotton has enunciated, but I do not express my opinion on the question how far it is possible by contract to exclude the right of applying to the Court under the Acts of 1867 and 1877, or how far the jurisdiction of the Court and the exercise of the jurisdiction under those sections is discretionary, or how far it is proper for the Court to consider the contract between the preference and other shareholders in determining whether they shall or shall not approve of the reduction. I do not express any opinion on those points, because they have not been fully argued, and although I express no dissent from what has been said by Lord Justice Cotton, I think it safer for myself, to consider they are still open questions. For these reasons I agree in the conclusion that this action must be dismissed, with costs.

Mr. Marten: As to the costs, will your lordship allow me to say that it appears that at the meeting the solicitor, speaking with the Chairman's permission, says, "It is extremely likely that some one will raise the question. I think I may say, with the Chairman's permission, that the Directors would not be sorry if some one would raise the question, as it would then make them perfectly clear, and save them from any anxiety in the future." What I submit to your lordships upon the question of costs is this, it is a matter which has arisen on the construction of the documents of the Company themselves, and also it was a matter on which the Directors suggested, through their solicitor, that they would be glad that there should be a decision, so as to make them perfectly safe in the matter. There have been contrary decisions, but the decision of the Court below was in our favour, and your lordships' decision against us.

Lord Justice Fry: Will they not be more glad, Mr. Marten, if you pay their costs?

Mr. Marten: No, my lord. What I should suggest is that the action should be dismissed without costs.

Lord Justice Fry: We cannot accede to that.

Cooks v. The Great Western Railway Company.

Lord Justice Cotton, in giving judgment in this case on Friday morning last, said that it was an appeal from the decision of Mr. Justice North, and was one of rather an extraordinary character. The action was first brought by gentlemen who were trustees of the Paddington estate, and occupiers of some of the houses there, and the object of the action was to restrain the Great Western Railway Company, who were also lessees of that estate, from breach of covenant which the plaintiffs alleged the defendants committed. When the case came on for hearing the railway company did not dispute that, and they submitted to the injunction. The injunction was not to be put in operation till the 19th of October, and it was practically to restrain a breach of the covenants, through the annoyance caused to the adjoining occupiers and owners of houses by the works for lighting with electricity the station and other portions of the Great Western Railway, near Westbourne-terrace. The plaintiffs moved, before Mr. Justice North, the previous week that a sequestration might be issued against the railway company, and his lordship did not refuse the application under certain circumstances, but made an order that the motion should stand over till the 11th of January. As he (Lord Justice Cotton) understood it, the judgment was on the basis that there had not been a compliance with the order of the Court—that was to say, that the defendants were guilty of a breach of the injunction, but the motion was made to stand over till the 10th of January. Against that there was an appeal, and it was extraordinary that there should be an appeal brought against the direction of a judge that the matter before him should stand for decision till a future period. The question was whether the judge was right in taking the course he did. The first question was whether the judge had discretion in such a case. Mr. Giffard contended that he had not—that it was the right of the plaintiff to enforce the order and to have the sequestration. That was, in his opinion, wrong, and, according to his interpretation of Order 42, Rule 31, as he understood Mr. Justice North's judgment, his lordship came to this conclusion, that there was a reasonable prospect on the evidence before him that by the time for which the order for sequestration was allowed to stand over had arrived the breach of the covenants would be remedied. He thought that was a proper mode for Mr. Justice North to exercise his discretion—whether on the evidence there was a reasonable prospect of the matter complained of being corrected by the railway company. When one looked at the nature of the case, before stopping the works of the railway company for lighting their station and adjoining works, one ought to consider alike the inconvenience to plaintiffs, and also the inconvenience and loss to the Company in stopping its works. Of course, if there had been wilful disobedience, he would not hesitate a moment in saying that the order must sternly be enforced—he meant wilful not in the sense in which it was used by Mr. Giffard, that every time they lighted their furnace they were committing wilful disobedience of the order, but an intention not to obey the order by removing the nuisance complained of. They had done what they could up to the present time to remove it. They had not, it was true, stopped their electric lighting, but they had done what they could to remove the nuisance. He ought to say that though he agreed in the course taken by Mr. Justice North, the railway company must not suppose that this Court would allow the order of the Court to be disregarded—that if there was no removal of the nuisance, or if there was no attempt to remove it, or if it turned out that it could not be removed, he would not for one moment suppose that the injunction would not be enforced. But was there the prospect which Mr. Justice North thought there was? Let them see what the matters complained of were, and whether there was any prospect of their being remedied. He would take first the smoke and steam. He himself was a little bit struck with the evidence as regarded the smoke and steam, because, as the matter was opened to the Court, it did not appear exactly how the getting the means of condensing the steam would remove the nuisance complained of caused by the smoke. It appeared, on the evidence, however, that the furnaces had been so constructed that they had the best contrivances for consuming their own smoke. The steam had not up to the present been effectually condensed. There was an effort to do it, but the chamber in which the steam was to be condensed was not made sufficiently strong, and after it had been two or three days in operation it had to be renewed. The company were taking, and he believed by this time had taken, very effectual means to construct a new chamber for the steam. How would that affect the smoke? It appeared that the amount of smoke escaping, although the furnaces were constructed according to the best method for consuming their own smoke was considerable. Even on the evidence, if there had not been sufficient provision for condensing the steam, that was what the Company were really trying their best to do; and as far as he could see there was every prospect that that would be done, as it undoubtedly could be done, and then both the steam nuisance and the smoke nuisance complained of would probably, as far as one could judge from the evidence, be remedied. Then as to the humming, which was one of the great complaints in the case. They had evidence that steps were taken before this motion was made to put a stop to the humming with a covering of wood, which, on the evidence, was very effectual. But the effect of raising the heat was to injure the coils in the dynamos, and therefore that would not answer. But according to the evidence the Company were taking steps to remedy the evil. The appellant's counsel treated what was being done as merely puerile efforts. He (Lord Justice Cotton) could not share that view. He was not an engineer, but there were many ways he should think by which the heating could be prevented. Having referred to the evidence of Sir Frederick Abel, Mr. Spagnoletti, and Dr. Hopkinson, his lordship thought there was every ground to suppose that the humming noise might be removed. Now, if suggestions were made which would, in the opinion of competent persons, remove the nuisance complained of, he would hesitate to order a sequestration without having an opportunity of seeing what those suggestions were, and of judging how far it could be said they were mere

Digitized by Google

nonsense or child's play. Then, again, on the evidence there was certainly a doubt to his mind whether there was any vibration at all. In conclusion, his lordship added that in his opinion Mr. Justice North was right in the course he took, and, as he had stated already and would now repeat, the railway company had hitherto been doing their best to remove the nuisance complained of, and there ought at present to be no sequestration to delay them in carrying out the means which were contemplated. If those means were effectual, then there would be a compliance with the injunction ; but if it could only be complied with by the removal of the electric light, then, of course, they must submit to that course, as the covenant was broken by the machinery as it at present existed. In his opinion, therefore, the application failed.

Lord Justice FRY said he was entirely of the same opinion. He considered the appeal was ill-founded, and must be dismissed.

The ATTORNEY-GENERAL having applied for costs they were allowed.

Callow v. Young.

In the Chancery Division of the High Court on Friday, Mr. Romer, Q C. (with whom was Mr. Oswald), instructed by Mr. Herbert F. Oddy, of 58, Lombard-street, applied to Mr. Justice Chitty for a writ of attachment to issue against one Frederick Young for non-observance of an undertaking into which he had by his counsel entered. Mr. Romer said that Mr. Young was the defendant in an action "Callow and Young," which had been brought by Mr. Callow, who was carrying on business as F. Young and Co., telephone, telegraph, and bell case manufacturers at Clerkenwell Green, to obtain an injunction preventing the defendant from carrying on any such business within 100 miles of the Royal Exchange. Young had formerly carried on the business, and had retired in favour of Messrs. Heaton and James, with whom he entered into a covenant not to have anything to do in any way with any similar business. Mr. Callow, the plaintiff, bought the interest of Messrs. Heaton and James, but ascertained that the defendant Young had commenced business at Lloyd's Row, Clerkenwell, as a telephone, telegraph, and bell case manufacturer, under the name of Carrington, and that he employed Carrington as foreman, holding him out as the proprietor, but being himself the real proprietor. Upon these facts being represented to Mr. Justice Stirling, a perpetual injunction was granted against the defendant Young, with an inquiry as to damages and costs. The application now made was for a writ of attachment for a breach of the undertaking entered into by the defendant Young. The defendant had not been served personally because he could not be found, but his solicitor had received the customary notice that this motion would be made. There might be some difficulty about that, and out of extreme caution he thought it desirable it should be mentioned ; but after a short argument and references to the orders of the Court the learned judge said he would accept the service as good, remarking that there was a difference between giving a man a notice of a breach of a voluntary undertaking, and notice of an adverse order which had been made against him. Mr. Romer then read an affidavit which had been filed by Mr. Oddy, the plaintiff's solicitor, and also other affidavits, which went to show that the undertaking given by the defendant Young had been broken by his setting up business under cover of Carrington's name, at Lloyd's-row, Clerkenwell.

Mr. Justice CHITTY said that that was sufficient to prove the plaintiff's case, and granted leave for the issue of a writ of attachment for the arrest of the defendant Young, with costs against him.

THE BLACKPOOL ELECTRIC TRAMWAY COMPANY.

The report of the Directors of this Company for the year ending 31st October, 1886, was issued on the 19th inst. The second annual meeting of shareholders is called for to-morrow (Saturday), at three in the afternoon, and the report runs as follows :—

The revenue account shows the sum of £5,125. 17s. 3d. as receipts, and £3,334. 14s. 7d. as working expenses, or a balance of profit for the year of £1,791. 2s. 8d. Adding to this £62. 7s. 6d. from last year in respect of the period from the opening (12th September) to 31st October, 1885, makes an available amount of £1,853. 10s. 2d., of which the Directors recommend the following appropriation :—

A dividend of 5 per cent. on £20,025 (the called up capital of the Company)	£1,001	5	0
Depreciation and reserve fund	800	0	0
Balance to next year	52	5	2
	£1,853	10	2

The Board consider the above result of the first full working year of the Company as satisfactory. Three directors, taken in alphabetical order, under the Articles of Association, retire at the meeting, viz.:—Messrs. Morris, Moseley, and Oddie, who are eligible for re-election. Dr. Scholefield having resigned his office as a Director of the Company in November, 1885, the Board then appointed Dr. Kingsbury, of Blackpool, to the seat so vacated. The Directors have not included in the accounts any charge for past services, and leave this matter to the general meeting of the shareholders. Mr. Broadbent's services as managing director have been secured again for the coming year. The capital and liabilities of the Company are shown to be as follows :—

2,850 shares £10 each, £6. 10s. called up (less £27. 10s. owing)	£18,525	0	0
Shares allotted as fully paid up to Mr. H. Smith, under his agreement	1,500	0	0
Sundry liabilities	852	4	4
Disposable balance	1,853	10	2

The following are the property and assets and preliminary expenses :—

Tram shed	£2,357	18	10
Engines, generators, motors, &c.	3,167	6	1
Centre channel and electrical fittings	8,354	14	3
Ten cars, &c.	1,784	3	3
Mr. M. H. Smith, being the consideration for the assignment of the Corporation concession and patent right for Blackpool	2,000	0	0
Engineer's commission	541	0	0
Miscellaneous capital expenses	556	5	1
Preliminary expenses	1,383	11	0
Stock	104	12	3
Debts owing to company	9	3	9
Cash in hand	2,444	10	0

On the revenue account the receipts are :—

Passenger receipts from cars	£4,960	17	3
Rents of advertising spaces on cars and tickets	165	0	0

The expenditure is detailed as follows :—

Horsing and driving cars	£115	9	11
Wages of drivers, conductors, checkers, ticket clerk, engineer, electrician, stoker, &c.	1,092	5	5
Electrical fittings, chains, collectors, &c., and repairs to electrical fittings, rewinding and repairing armatures, collectors, and other sundry repairs	301	2	5
Coke, coal, and oil	270	13	5
Ironmongery and smiths' work	75	4	11
Timber and joiners' work	28	12	0
Rent for year at 6½ per cent. per annum on cost of line (£11,137. 8s. 9d.) payable to Corporation of Blackpool under agreement	723	18	8
Rent of ground for tram shed, from December 31st, 1885, to 31st October, 1886, at £35 per year, and rent of office, North Shore	45	13	10
Income tax on profits, and rates and taxes on office, North Shore	42	13	1½
Gas and water	69	1	5
Advertising, printing, and stationery	45	6	8½
Salaries of managing director, secretary, manager, and auditor	221	10	0
Directors' expenses	65	11	3
Fire and employers' liability and insurance premiums	45	8	9
Law charges	12	8	7
Bank interest and commission	85	0	7
Miscellaneous expenses	94	13	7
Profit and loss for net revenue	1,791	2	8

NOTES.

SOUTHAMPTON TELEPHONE EXCHANGE.—This exchange now numbers 42 subscribers.

VIENNA.—The Vienna General Post Office is being fitted with about 350 incandescent lamps.

TRANSIT TABLES.—We have received from Messrs. Spon a copy of "Transit Tables for 1887," by Latimer Clark, F.R.A.S.

DIARIES.—Messrs. Griffith, Farran, and Co., send us a copy of the well-known "Blackwood's Shilling Scribbling Diary" for 1887.

CANAL LIGHTING.—The banks of the Canal de Donai are to be lit by electric light, in order to enable the navigation to proceed by night.

CHURCH LIGHTING.—The church at West Hanney, Berks, has been lit by electric light. The work was carried out by Mr. Stroud, of Wantage.

THE BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 26th November amounted to £4,396.

GLASGOW TRAMWAYS.—The Glasgow Tramway Company is seeking powers "to employ mechanical or electric in addition to animal power," for working its lines.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November amounted to £50,817, and to £56,245 in the corresponding period of 1885.

SUBMARINE NAVIGATION.—A new submarine boat for naval warfare was tested last week at the West India Docks, with very satisfactory results. This boat is propelled and lighted by electricity.

CABLE INTERRUPTED.—The cable between Trinidad and Demerara is interrupted. Until repairs have been effected this will entail a delay of three or four days on telegrams for British Guiana.

FATALITY FROM LIGHTNING.—During a heavy storm at the Kimberley Diamond Fields, eight men at the bottom of a pit were struck by lightning; one was killed, and the others severely injured.

LECTURE ON THE ELECTRIC TRANSMISSION OF POWER.—On 25th November Mr. William Lant Carpenter, B.A., B.Sc., delivered a lecture on the Electric Transmission of Power, before the Bradford Philosophical Society.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November amounted to £36,739, and to £40,427 in the corresponding period of 1885.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 26 were £3,637, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE "SPECIALISTS' SERIES."—We have received from Messrs. Whittaker and Co. a copy of the eighth volume of the "Specialists' Series," "On the Conversion of Heat into Work," a practical handbook on heat engines, by Mr. William Anderson, M.Inst.C.E.

PROJECTED PACIFIC CABLE.—A *Times* telegram reports the formation in New Zealand of the "Pacific Cable Company," which proposes to lay a cable from Brisbane *viâ* New Zealand, the Fiji and Sandwich Islands, to Vancouver, where it will connect with the Canadian system.

THE SOUTH KENSINGTON SCIENCE SCHOOLS.—We learn that Prof. Rücker, F.R.S., has been appointed by the Lord President of the Council to the Professorship of Physics in the Normal School of Science and Royal School of Mines, rendered vacant by the death of Prof. Guthrie, F.R.S.

"LIVES OF THE ELECTRICIANS."—We have received from Messrs. Whittaker and Co. a copy of the first volume of this series, to which we referred last week, containing biographies of Profs. Tyndall, Wheatstone, and Morse. We regret that pressure upon our space compels us to hold over a more detailed notice until next week.

THE EDINBURGH EXHIBITION AWARDS.—Messrs. Laing, Wharton, and Down ask us to mention that Mr. Miller, of Glasgow, is the agent for the Thomson-Houston system north of the Tweed, and that the gold medal obtained by the Thomson-Houston system at the Edinburgh Exhibition was awarded to Mr. Miller.

SALE OF MACHINERY.—On December 7th, 8th, and 9th, at the Alliance Engineering Works, West Drayton, near Uxbridge, Messrs. Wheatley Kirk, Price, and Goulty will sell by auction a quantity of machinery. The sale on the third day comprises a number of slotting, drilling, and planing machines and lathes of various kinds.

COLLIERY DISASTER.—We regret to learn that yesterday (Thursday) morning, at ten o'clock, a severe explosion occurred in a colliery at Ellmore, near Durham, which has been lit by electricity. It is feared that from ten to twenty lives have been lost. The dynamo house—apparently at the bottom of the shaft—was found to be in flames.

DIRECT SPANISH TELEGRAPH COMPANY.—Notice is given in the *London Gazette* of Tuesday that the petition presented to Her Majesty's High Court of Justice (Chancery Division), on the 26th ult., for confirming a reduction of the capital of the company from £190,000 to £95,000 is directed to be heard before Mr. Justice Kay on the 11th inst.

THE SOCIETY OF TELEGRAPH-ENGINEERS.—The annual general meeting of the Society of Telegraph-Engineers and Electricians will be held at the Institution of Civil Engineers at 8 p.m. on Thursday, December 9th, when the president, vice-president, members of the council, and other officers of the society will be elected for the year 1887.

MEXICO.—We learn that an exhibition of electrical appliances is being held this month in the City of Mexico. The streets of Mexico have been supplied with electric light for over two years. The plant is now to be extended by the addition of 40 arcs. The town of San Luis, Potosi, has ordered the erection of the same number of arcs for street lighting.

PENZANCE.—The *Royal Cornwall Gazette* states that the public subscription which is being raised in Penzance in order to light the streets of the town by electricity has resulted very favourably so far, and in all probability the matter will shortly be proceeded with. The Gas Company have, as usual under similar circumstances, been aroused to action, and are putting in a number of extra powerful burners in several parts of the town.

TELEPHONY IN GERMANY.—The *Centralblatt für Electrotechnik* announces that the trunk line between Munich and Augsbourg has been completed, and the results are very satisfactory.—The town of Wurzbourg is to be provided with a telephone exchange.—Upon the German State lines Siemens transmitters have been exclusively employed hitherto; these are now to be given up in favour of a transmitter of the simple microphone type.

Digitized by Google

SPANISH TELEGRAPHS.—From the latest report of the Spanish Minister of Posts and Telegraphs, we learn that during the six months to which the report refers, 30 new telegraph offices were opened in the country, involving the addition of 167 kilometres of wire. There are at present open 533 State offices and 359 belonging to the railways. The total number of despatches transmitted during the half year was 1,332,394, including 342,202 foreign.

SPANISH TENDERS.—In addition to the tenders for the supply of telegraph posts in several provinces of Spain, to which we lately referred, it is announced that tenders will also be received on the 26th instant for the supply of 5,500 posts for Segoria and Avila, viz., 2,500 of a length of six metres, at a maximum price of eight pesatas each; 2,500 of seven metres, at a maximum of nine pesatas; and 500 of eight metres, at a maximum of 10 pesatas each.

SOCIETY OF ARTS.—We would remind our readers of the paper on "Glow Lamps, their Use and Manufacture," to be read before the Society of Arts on the 8th inst. by Major-General C. E. Webber. At the meeting after Christmas the following papers (among others) will be read:—"On the Development of the Mercurial Air Pump," by Prof Silvanus P. Thompson; "On Progress in Telegraphy," by Mr. W. H. Preece; and "On Electric Locomotion," by Mr. A. Reckenzaun.

TELEGRAPHS IN THE ARGENTINE REPUBLIC.—From a report recently issued we take the following figures relating to last year's working of the telegraph system in the Argentine Republic:—The total number of messages transmitted was 658,000, showing an increase of 15 per cent. over the preceding twelve months. The receipts amounted to $271,000, and the expenditure to $515,000, leaving a deficiency of $244,000. During the last five years 4,190 miles of wire have been erected, the total mileage being now over 7,400.

LECTURE ON ARTIFICIAL LIGHTING.—A lecture on "Artificial Lighting" was delivered last week by Mr. John Slater, B.A., before the advanced class of construction at the Architectural Association. Mr. Slater strongly endorsed the advantages of electric lighting, and gave some figures with regard to the cost of an installation of 50 lamps. In the report now before us he is made to say that "23,360 hours' light" can be obtained "at an average cost of 2½ farthings per hour." We do not profess to understand this, but no doubt the reporter is alone to blame.

MADRID.—In connection with the scheme for a central lighting station at Madrid, which has been taken in hand by the "Mercantile Club" of that city, two representatives of the club have been deputed to visit the principal cities of Europe in which electric lighting on any large scale has been adopted with a view to the selection of a system. The deputation had arrived last week in Milan. Unhappily, we fear that there will be little inducement for them to visit this country. On their return they will issue a report which will possibly prove interesting.

THE "MONARCH" CABLE SHIP.—During one of the recent storms a vessel was wrecked upon the north coast of the Isle of Man, close to the point where the three wire cable comes on shore. The cable received some damage, though not sufficient to stop working. The repairs were effected by the "Monarch" on the 24th ult. She left Holyhead at 3 a.m., made the passage to the island through a thick fog, picked up the cable, located the fault, cut it out, and had all made good by 3 p.m. the same day. Mr. Lumsden, chief electrician, assisted by Messrs. Cully and Pollard, were in charge of the operations.

THE LIGHTING OF RAILWAY CARRIAGES.—The *Pall Mall Gazette* has recently published several letters containing bitter and certainly well-founded complaints as to the lighting of the carriages employed in the suburban traffic of many of the leading companies. The Brighton and South Coast line seem at length to have satisfied themselves as to the practicability and efficiency of the system of electric lighting which they have for some time employed upon a small scale, and, as we recently mentioned, are about to extend its use. If the public will only take the trouble to keep up the agitation there is little doubt that other lines will eventually follow their example.

THE ELECTRIC LIGHT AT VIENNA.—A rather curious state of affairs exists at Vienna with regard to the long-projected central electric lighting station in that city. Some time ago the municipal authorities placed their veto upon the scheme as it then stood. Now, however, according to *La Lumière Electrique*, the Minister of the Interior has granted authorisation to the same parties to whom it had been refused by the municipality. We do not know whether the Ministerial decision absolutely overrides that of the municipal authorities, but the upshot seems to be that negotiations have been reopened between the latter and the authors of the scheme.

THE GAULARD-GIBBS SYSTEM.—The National Company for the Distribution of Electricity by Secondary Generators informs us that they have received information by cable of the successful opening of an installation of 4,000 lamps under the Gaulard-Gibbs system at Buffalo by the Westinghouse Electric Company. This work has been carried out in a remarkably short time. It appears that two months ago, when one of the principals of the Westinghouse Electric Company (now in England) left the States, even the negotiations for this installation had not yet been commenced. We should like to know whether the distribution is effected in parallel or in series connection in this case.

A QUERY RE TRANSFORMERS.—*Apropos* of the forthcoming action Gaulard-Gibbs *v.* Ferranti, one of our French contemporaries not unnaturally asks how it is that the only extensive installation of transformers which has been carried out on the Gaulard-Gibbs system in this country should have resulted in acknowledged failure, while in France, and notably at Tours, the Gaulard Gibbs transformers have given perfect satisfaction. We are under the impression that the answer will be found in the fact that the economical advantages attending the use of transformers has at Tours been largely sacrificed to the simplicity of regulation which is afforded by the use of a parallel system of connection. In this country economy must always be the first consideration.

LIGHTNING.—Since it has become possible to study the path of a lightning flash by means of electricity, several interesting observations have been made which we have from time to time recorded. It has recently been established by Herr Leyst, of the Pawlowsk Observatory, that a flash not unfrequently divides into two or more branches. In one case a flash divided into two branches, forming an angle of about 75°; then, after traversing a certain space, the branches turned towards each other, and presently reunited, thus forming a quadrilateral figure. In another interesting flash the same identical path was lit up four times in succession at short intervals. The thunder which followed lasted 80 seconds.

LIGHTING OF A FERRY STEAMER.—Messrs. J. D. F. Andrews and Co., of Glasgow, have just completed an installation on board the Tay ferries steamer at Dundee. The boat is luxuriously fitted up throughout, and the electric light fittings are in accordance with their surroundings. The dynamo is

Digitized by Google

one of Andrews' slow-speed, self-regulating type, running at 590 revolutions, and driven by belting from a Tangye engine. A 10-ampere arc lamp, of 1,000 candle-power, is carried on a flag pole at a height of 30ft. above the deck, and is used at the landings for lighting the gangways. We understand that during the last two years Messrs. Andrews have fitted a total of very nearly 10,000 lamps on steamers of various kinds.

Welding by Electricity.—On this subject we have received a letter from Mr. Radcliffe Ward, who wishes to call attention to the fact that in the year 1884 Captain W. Blanch Brain, who was at one time associated with Mr. Ward in connection with the British Electric Light Company (now defunct), was at work upon experiments connected with welding by electricity. Mr. Ward thinks it probable that Captain Brain has therefore a claim to priority in this matter over both Prof. Elihu Thomson and Mr. Duncan. Mr. Ward also states that Captain Brain had succeeded in obtaining a return of 80 per cent. in the electric transmission of energy "at a time when men more purely scientific held that 50 per cent. was the possible maximum."

Effluviography.—This euphonious name has nothing to do with the science of ill-odours, but has been applied by M. D. Tomassi to the effects produced by the silent discharge upon a sensitised gelatine-bromide plate. After an exposure of some minutes' duration an image may be obtained from an electrified body, although (if we understand the author aright) the potential may not be high enough to give any sign of light, and when all other light is excluded. The image may be developed in the usual manner. M. Tomassi considers that the silent discharge produces the same effect as the ultra-violet rays, and may form a connecting link between the two extremes of the spectrum, consisting of what may be called "electric rays." But we doubt whether this suggestion will obtain any wide acceptance.

Telegraph Clerks and the Royal Commission.—An enthusiastic meeting of the Post Office telegraphists was held in Liverpool on Saturday evening, when great satisfaction was expressed at the appointment of a Royal Commission to inquire into the working of the Civil Service. Discontent and agitation had, it was stated, been rife in the telegraph service ever since its transfer to the State, and the staff were determined that, so far as their department was concerned, no effort on their part should be spared to enable the inquiry of the Commission to be searching and thorough. Resolutions were unanimously passed condemning in strong terms the present system of promotion by selection, as giving opportunities for favouritism and injustice, and an earnest hope was expressed that the commission would not only recommend a more equitable system, but make close inquiry into the fairness of past promotions, and into the mode of exercising those absolute powers in this and other directions which the surveyors practically, though not nominally, possess. A committee was appointed to prepare and lay before the surveyor of the district a statement of information wanted.

The Early Progress of Telegraphy.—In the year 1844, seven years after the practicability of the electric telegraph had received complete demonstration, it was still possible for a paragraph such as the following to appear in *The Times* (April 14th, 1844):—"The first intelligence of the arrival of H.R.H. Prince Albert in this country from Germany, on Thursday last, was communicated to Her Majesty at Windsor Castle by Galvanic telegraph on the line of the Great Western Railway. Within one minute of the arrival of H.R.H. at the Paddington terminus the information had reached Slough, at which station a special messenger, mounted upon one of the fleetest horses in the royal stables, was stationed, by command of the Queen, who proceeded with the gratifying intelligence to the castle, where he arrived in eight minutes and a half from the time of leaving Slough. Thus the news of the Prince Consort's return to England reached Her Majesty, and their Majesties, the King and Queen of the Belgians, in less than 10 minutes after his royal highness had arrived at Paddington, and 40 minutes before the prince had reached the royal residence at Windsor."

Long Distance Telephony.—In the year 1884 the American Bell Telephone Company determined to undertake a series of elaborate trials and experiments in long-distance telephony. For this purpose a special test line, 300 miles in length, was erected between Boston and New York, and for more than twelve months experiments were carried out under all conceivable conditions, and with every known form of instrument. The line itself was of hard drawn copper, and the experiments were chiefly directed to the determination of the best means of avoiding inductive disturbance, and to the discovery of the most suitable transmitter. With regard to the latter point, it is certain that the chief object to be aimed at is the use of comparatively large currents while retaining the necessary delicacy of action. From a circular recently issued by the company we understand that they have succeeded in developing a satisfactory transmitter, which is ascribed to the conjoined labours of Blake, Edison, Berliner, Gilliland, Hughes, Hunnings, and others, but of which the precise construction does not appear. As for the elimination of induction, the company has arrived at the conclusion that the necessary and sufficient condition is the use of a metallic circuit. With these arrangements conversation over the three hundred miles from Boston to New York is now thoroughly practicable and satisfactory. In order to be able to avail themselves of this extension, we understand the local telephone exchanges in New York, Brooklyn, and the adjacent towns are now taking steps to provide their subscribers with metallic circuits.

Extraordinary Medical Experiments.—A Paris correspondent of one of the daily journals says:—"The chief French surgeons and medical professors have for some time been carefully studying the effects of mesmerism on the female patients of the Salpêtrière Hospital, and M. Babinski, a clinical surgeon of that establishment, has just effected a series of experiments, the results of which would seem to open up a new future for medical science. M. Babinski tried to prove that certain hysterical symptoms could be transferred by the aid of the magnet from one patient to another. He took two subjects, one a dumb woman, afflicted with hysteria; and the other a female who was in a state of hypnotic trance. A screen was placed between the two, and the hysterical woman was then put under the influence of a strong magnet. After a few moments she was rendered dumb, while speech was suddenly restored to the other. M. Babinski also effected temporary cures of paralysis in the same manner." We would suggest to M. Babinski that he should repeat his experiments with pieces of wood or copper of the same size, shape, and colour as his magnets, when we have not the least doubt that precisely the same measure of success would be attained. It is a great pity that the exploded fallacy of "curative magnetism," which so readily lends itself to the purposes of the charlatan and the quack, should receive the least countenance from any one claiming to be an authority in medicine. The employment of *electricity* in therapeutics stands upon a totally different basis, although its true function and limitations still

Digitized by Google

remain to be worked out, and afford a most legitimate field for inquiry.

Pictures Produced by Lightning Flashes.—The American Institute has recently had a lively discussion over the photograph of a young lady which was alleged to have been due to the direct action of a flash of lightning. As we mentioned some weeks ago, the picture in question appeared upon the surface of a brass plate which the young lady was holding in her hand at the time of a severe thunderstorm. During the discussion at the American Institute, Mr. T. C. Martin read the following paragraph, which appeared in *The Operator* for January 1, 1876:—"We learn that within the last two weeks a singular discovery has been made at the house of Jesse Garth, for many years deceased. It is said that a distinct and accurate likeness of Mrs. Garth, who has been dead for twenty years, can be seen on a pane of glass in the upper sash of one of the windows, presenting very much the appearance of a photograph negative. The discovery is said to have been made by a woman who was washing clothes in the yard, who imagined some one was watching her through the window, and went inside to see who it was. We gather these facts from Dr. Charles Brown, who has himself seen the singular picture. Dr. Brown remembers that about twenty years ago Mr. Garth told him that his wife, while standing at the window, was stunned by a sudden flash of lighting, and the doctor's theory is that the outline of her features was photographed on the window at the time. The youngest daughter of Mr. Garth, and others who were acquainted with Mrs. Garth, have seen the picture and pronounced it a striking likeness."

The Management of Accumulators.—We have received a copy of a pamphlet of twenty pages, entitled "The Management of Accumulators," by Sir David Salomons. The author expresses a hope that the subject will be found "to have been made clear to the understanding of the majority of those whose daily routine deals with electric lighting accompanied by an accumulator." Sir David's wide practical experience upon this subject is well known, and we would cordially recommend this little work to those for whose benefit it is primarily intended, feeling sure that as regards all practical details of the management of the cells—and many such details have to be attended to if the installation is to be worked with success and economy—the author's anticipations will be fully realised. Upon certain of the more theoretical points Sir David has arrived at conclusions rather different from those which are usually entertained, but this feature will detract little, if at all, from the value of his practical observations. The description of the accumulator room at Broomhill, which has been specially built for the purpose, and is equipped with every possible appliance for facilitating the manipulation of the batteries, will be of interest to all; but, unfortunately, we fear that the number of consumers who could be induced to fit up a battery room "regardless of expense" is but very limited—the first convenient cellar is the usual destination of accumulator cells. One very simple "dodge" of Sir David's we may mention for the benefit of our readers. To avoid the nuisance of the acid fumes, and the very perceptible weakening of the solution caused thereby, it is found perfectly effective to place slips of glass at an inclination over the cells; the spray then collects in drops and falls back into the liquid.

The Electric Light at San Francisco.—A correspondent of the French journal, *l'Electricité*, gives an interesting account of the development of the arc light at San Francisco. The work is entirely in the hands of the California Electric Light Company, who hold a license for the Brush system. The central station at San Fransisco was one of the very first to be established, dating back to the year 1879, when the company commenced operations with a single Brush machine and six 2,000 candle-power lamps. The hours of lighting were from dusk to midnight, and a rental of $10 per lamp per week was charged. In January, 1880, the number of machines had increased to four, furnishing current to 64 arcs, while the price was reduced to $7 per week. In the month of April the station was destroyed by fire; but in less than four weeks the plant was again in working order. Since that period the number of arcs has steadily increased, and now exceeds 400. The original machines have been replaced by the new Brush pattern with improved armatures, each furnishing 60 to 65 arcs of 2,000 candles. Four steam engines are employed, supplied with steam by five tubular boilers. (Further particulars as to motive power are not given.) The conductors are of 4 mm. diameter, covered (only) with platted and varnished cotton. The lines are carried upon posts through the streets. There are several circuits of which the longest is over 12½ miles in extent. The rental has been reduced to $5 per lamp per week for lamps burning till midnight only, and $7 for those burning all night. The cost of installation, maintenance, and carbons is undertaken by the company. San Francisco also possesses a large number of isolated installations of incandescent lamps carried out chiefly by the Edison Company.

The Electrolysis of Ammonic Sulphate.—At the meeting of the Chemical Society, on the 18th inst., a preliminary note on "The Electrolysis of Ammonic Sulphate" was read by Mr. Herbert M'Leod, F.R.S., as follows:—"When a neutral solution of ammonic sulphate is electrolysed in a U-tube provided with platinum plates as electrodes, nearly pure oxygen is evolved at the positive pole and hydrogen at the negative. For one volume of gas from the positive pole a quantity varying between 4·7 and 5·4 volumes is evolved from the negative pole. A small amount of ozone is produced. On mixing together the electrolysed liquid at the poles a strongly alkaline liquid is obtained, containing a considerable quantity of "active" oxygen. When the liquid is first neutralised with sulphuric acid, then treated with excess of baric chloride, and the baric sulphate filtered off, the liquid deposits baric sulphate on boiling, an indication of the presence of persulphuric acid in the solution. When sulphuric acid that has been electrolysed is exactly neutralised with baric hydrate, the precipitate filtered off and the liquid boiled, baric sulphate is precipitated; at the same time the liquid becomes acid and a further quantity of baric sulphate is thrown down on the addition of baric chloride." In reply to a question by the President, Prof. McLeod said that Faraday in the experiments which gave results differing from those now described, had used an alkaline solution of ammonium sulphate in ammonia. Dr. Messel asked if the deficiency in oxygen might not be due to the formation of hydrogen peroxide. In experiments on the electrolysis of sulphuric acid solution (with a current of 60 amperes), he had at all events observed the characteristic colour on application of the chromic acid and ether test. Prof. McLeod said that he had always failed to detect hydrogen peroxide.

Proposal for Lighting Trains in Tunnels.—During the last few years several of the French railways have employed a very simple method, which seems to have been first introduced by M. D. Baillebache, for automatically signalling the passage of a train. This method consists in separately insulating one or more of the rails, and connecting them by an insulated wire with a bell at the signal station. When the train runs over this part of the line, the circuit is

Digitized by Google

completed through the wheels to earth. M. de Baillebache now proposes to employ a modification of this arrangement in order to automatically light the train while passing through tunnels. Instead of insulating the rail itself, he lays an insulated copper strip along one side of the rail in such a position that the flanges of the wheels make good contact with the copper. The circuit is then completed to earth as before. These are all the details which have as yet appeared; we suppose, however, that M. de Baillebache has not overlooked the fact that in such an arrangement it would be necessary also to insulate the tyre of the wheel from the axle and the body of the carriage. As a more practicable modification, we would suggest the use of a trailing collector placed in the guard's van, and arranged to be lowered upon the insulated strip when required. Secondary batteries would, of course, be employed, and as there would be little or no difficulty or expense in removing them to a convenient station for re-charging, the system would certainly seem to be worth attention. Upon some lines where tunnels are long or numerous, as for instance on the Great Western Railway between Corsham and Bristol, the arrangements for temporarily lighting the trains are a source of considerable trouble and expense, as well as loss of time, and it might easily be found on investigation that some such method as that proposed would prove a decided gain in economy as well as efficiency. Since writing the above we have learnt that a very similar scheme was proposed some years ago by Mr. Crompton for lighting the Metropolitan and District lines.

The Telephone at Preston.—The town of Preston has for several years occupied a peculiar position in matters telephonic. In the year 1881 an exchange was opened by Mr. G. Sharples, a local electrician, which met with a very considerable success. A little later the Lancashire and Cheshire Telephone Company came into the field, and started a rival exchange. The result was that the Preston public (as some compensation for the inconvenience of having two separate and distinct telephone systems) got their connections made at a remarkably low figure. Indeed, for some considerable period the rival exchanges were willing in some cases to accept customers absolutely "free gratis for nothing." The rates were afterwards raised from £6 to £8 per annum, which still allowed the Preston people to boast of having the cheapest telephone system in the country. At length, however, the inevitable amalgamation has been effected, Mr. Sharples' exchange has been purchased by the Lancashire and Cheshire Company, and the rates will be raised to £10 all round. The subscribers will, however, scarcely have any reason to grumble at the change; the inconvenience of the two separate systems had grown to a serious evil, and in addition to the advantage of getting rid of this source of annoyance, the subscribers to the local exchange will now be enabled to avail themselves of the system of trunk lines by which all the chief towns in Lancashire and Cheshire are connected. As some further consolation for the increase of tariff we understand that the company proposes to allow communication between Preston and the principal sea-side resorts on the Lancashire coast free of extra charge. This has reference to the towns of Blackpool, Lytham, St. Annes, and Fleetwood. The total number of subscribers now approaches 500. The instruments employed in the local exchange were those of the original Bell Company, of which Mr. Sharples had, with admirable foresight, purchased a large number in the early days when telephones could be bought and sold outright. With equal discrimination in disposing of his exchange to the Lancashire Company, Mr. Sharples has retained the whole of these instruments in his own hands, and these he will shortly place upon the market.

Unsuspected Dangers with Frictional Electricity in Blasting.—In the New York *Electrical World* Mr. W. E. Irish writes as follows:—"Some years ago, when I was engaged in assisting to carry out a series of experiments in the firing of torpedoes and mines by means of electricity, an incident occurred which nearly resulted in a most serious calamity. About a week after the commencement of a long series of experiments several charges of gunpowder, gun-cotton, and dynamite were submerged in a river about 100ft. apart, the object being to learn what the effect of each would be when fired under the same conditions. The firing station and position of the charges in the river were on this occasion totally obscured from each other and about one mile apart. The cable employed consisted of a stranded copper conductor well insulated with 'Hooper's compound.' Two lines were used for firing the charges, and a third cable was laid for communicating between the two points by telegraph. The three cables were laid on the grassy land parallel to, but separated from, each other by a space of a few inches throughout the greater part of their length. Electricity for firing the charges was obtained from Baron Von Ebner's ebonite-disc frictional machine, which is too well known to need description. The two ends of the cables at the river were each connected to a charge, while at the firing station one end was carefully sealed and suspended in the centre of the firing room as a precaution and guard against the possibility of its coming in contact with the firing battery or machine. The other end was connected to the electric generator in connection with the charge to be fired first. Final arrangements having been completed and all made ready, instructions were telegraphed to fire No. 1, charge, which was carefully and correctly done. Scarcely, however, had the firing key been depressed when word was wired from the river 'to stop further operations, and leave everything at the firing station in the exact position it then occupied, as two charges had been fired instead of one only, as directed; and that in consequence a boat and party of men engaged near the charge which ought not to have been fired had most miraculously escaped being blown to pieces.' This was declared by the operators at the firing station to be impossible through any action or neglect on their part. The matter, however, was too serious to be left without a thorough and searching investigation. A very careful examination and insulation test of the end of this cable in the firing station proved that it had not been injured or tampered with in any way. It was determined to unravel the mystery, if possible, and we were not long in discovering that under precisely the same conditions the same result was always obtained. It was satisfactorily proved that detonation was not the cause, and eventually it was discovered that the firing of the second charge was due to induction. To remove all doubt two half miles of the same description of cable were placed one foot apart throughout their entire length, fuses been connected to the cables at one end to represent the charges, and the wire being then grounded as before. To one of the cables at the firing station the frictional machine was connected, while the other end was carefully sealed and suspended in the same room as before and at least ten feet away from the electric generator. The discs of the machine were given twenty revolutions and the condenser was discharged, when both fuses fired. Further tests led to the conclusion that it would be dangerous on cables running parallel and within 40 or 50ft. of each other, to employ the frictional machine where more than one charge is connected. The frictional machine was now removed, and tests were made with dynamic machines and voltaic batteries, but in no case did we succeed in firing more than the one charge, even when the wires were close together."

Digitized by Google

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 52.)

In constructing a dipping needle the steel bar is accurately balanced about its centre of gravity before it is magnetised. After magnetisation it will then take up the line of magnetic dip. As it is not easy to support a needle so that it is free to turn in every direction about its centre of gravity, dipping needles are generally balanced on a knife edge, like the beam of a balance, so that they are free to turn in a vertical plane, and this plane is made to coincide with the magnetic meridian by turning the instrument by hand. If such a dipping needle be placed with its plane of motion perpendicular to the magnetic meridian the needle will assume a vertical position, for the horizontal component of the earth's force will now have no tendency to turn the needle, and the vertical component will be left to act alone.

When a needle is magnetised it is impossible to secure the exact coincidence of the geometrical axis and magnetic axis of the needle. In determining the magnetic dip the inclination of the geometrical axis is read by the graduated scale, but the magnetic axis may be inclined at a greater or less angle than the geometrical axis. By raising the needle from its bearings and replacing it inverted the magnetic axis will be retained in the same direction, but the geometrical axis will in the second case be as much above (or below) the magnetic axis as it was formerly below (or above) it. The mean of the two readings of the geometrical axis will be the true reading for the magnetic axis.

But the magnetic axis itself may be deviated from the direction of the earth's force on account of the axis of rotation not passing through the centre of gravity of the needle. The usual mode of correcting this error is to demagnetise the needle and magnetise it in the opposite direction *to the same strength as before.* The ends of the needle being now reversed, if another pair of readings be taken and the mean of these determined, the mean of the two means will be the true direction of the dip. Care must be taken that the strength of the needle when remagnetised is the same as before, and this can be determined by counting the number of vibrations it can execute in a minute under the earth's action.

The difficulty arising from the want of coincidence between the geometrical and magnetic axis of the needle arises also with the ordinary compass needle, or declination magnet. It can be entirely obviated by inverting the needle upon its pivot, or suspension fibre, for the magnetic axis will remain in the same direction whichever face of the needle is uppermost, while the geometrical axis will make equal angles on opposite sides of the magnetic axis in the two positions of the needle, so that the mean of the readings of the geometrical axis, or of any other line drawn upon the needle, will be the true reading for the magnetic axis.

In magnetic observatories it is usual to register continuously the declination, the horizontal intensity, and the vertical intensity. From the two latter the total intensity and the dip can be determined as above explained.

The method of registration consists in causing a beam of light to be reflected from a small mirror attached to the magnet whose motion is to be recorded, and converged upon a piece of sensitised paper which completely surrounds a cylinder. The cylinder makes one rotation in 24 hours, being driven by a train of clock-work. If the magnet remains stationary, the spot of light will describe a straight line on the paper, but if the position of the magnet vary its motion will be recorded by irregularities in the line.

The declination is registered by means of a magnet suspended by a single fibre. This declination magnet always sets in the magnetic meridian, changing its direction as that of the meridian changes, since there is no sensible torsion to counteract the influence of the earth's force.

The horizontal intensity is registered by a *bifilar magnetometer.* This is a bar magnet suspended from a torsion head by two threads. The torsion head is turned so that the magnet is compelled, under the action of the suspension threads, to set with its magnetic axis at right angles to the magnetic meridian. The couple exerted by the threads when the needle points east and west is then experimentally determined, as well as the change produced in the value of this couple when the needle turns through one degree in either direction. The magnitude of the couple will depend on the weight of the magnet and its appendages, the distances between the threads at the top and bottom, and their length. If the horizontal intensity increases the north end of the needle will be pulled towards the north, notwithstanding the opposition of the bifilar suspension, until the increased angle between the threads of the bifilar causes their tension to balance the increased couple exerted by the earth. If the horizontal intensity diminishes, the bifilar suspension will cause the magnet to turn through a corresponding angle, in opposition to the earth's action.

The vertical intensity is registered by the *balance magnetometer.* This consists of a bar magnet capable of turning in the plane of the magnetic meridian, and so supported that it rests with its magnetic axis nearly horizontal. To effect this there is a small weight capable of sliding along the bar, and this is pushed, in north latitudes, towards the south pole of the magnet, until the moment of its weight balances the couple due to the vertical component of the earth's magnetic force. If the vertical intensity increase, the north pole of the magnet will dip through an angle nearly proportional to the increase, like the beam of a balance when there is a slight excess in one scale pan; if the vertical intensity diminish, the magnet will dip towards the south. The cylinder which carries the sensitised paper for the balance magnetometer turns about a vertical axis, and the spot of light moving up and down as the vertical intensity varies, a curve recording these variations is delineated.

When magnetic measurements are made in localities where there is no fixed observatory, the unifilar magnetometer is employed, together with a dip circle. By these instruments the declination, the horizontal intensity, and the dip are observed, and hence the vertical intensity and the total intensity can be immediately determined. The horizontal intensity is determined by the unifilar magnetometer from the number of swings executed in a minute by a magnet suspended in a wooden box by means of a silk fibre. From the moment of inertia, and the number of swings executed in a minute, the horizontal couple acting on the magnet can be inferred. This couple is equal to the product of the magnetic moment M of the magnet, and the horizontal intensity H of the earth's magnetism. In order to determine the value of the quotient of the magnetic moment M, divided by the horizontal intensity H, the magnet is placed at a certain distance from a compass needle, which is suspended by a single silk fibre, and the deflection produced in the needle is measured, the magnet being moved as the needle turns, so that the axis of the magnet may always be in the line drawn through the centre of the needle at right angles to the axis of the needle. The magnet is then said to be "end on" to the needle. Having determined the product M H and quotient $M \div H$, the values of M and H can at once be found.

The horizontal intensity is greatest at the magnetic equator; the total intensity is greatest near the poles.

Œrsted, in 1819, showed that when a wire conveying a current is brought near to a freely suspended magnetic needle, forces are introduced tending to make the needle set at right angles to the wire. The experiment was the starting point of the galvanometer and of the electric telegraph.

Faraday shortly afterwards showed that the action discerned by Œrsted was due to a force in virtue of which each pole of the magnet tended to revolve continuously around the wire conveying the current—the north pole in one direction, the south pole in the opposite direction. As the poles are held together by the material of the magnet, it is clear that in Œrsted's experiment this continuous rotation cannot take place, but each pole tending to go as far as possible in its own direction, the magnet will at length become at right angles to the wire. The needle will then be exposed to tension and to a bending moment; but there will be no further tendency to cause it to turn about its point of support. If the magnet could be rendered perfectly flexible the north pole would go round the conductor in one direction, and the south pole in the other, until the magnet had completely wound itself up in a tight coil around

Digitized by Google

the conductor. The character of the force around the conductor may be exhibited in iron filings just as in the case of magnets. If a small hole be made in a card and a wire conveying a current be made to pass through the hole at right angles to the card, and if iron filings be scattered on the card and slightly shaken, the filings will arrange themselves in concentric circles around the wire. Thus the lines of magnetic force around a straight wire which conveys a current are concentric circles round the wire. The direction of the magnetic force is given by the following rule :—

A current flowing in a conductor will tend to make the north pole of a magnet move round the conductor in the direction in which a right-handed screw would rotate if advancing with the current, and screwing its way through a solid.

The south pole of a magnet will, of course, tend to revolve in the opposite direction, and since the force on the south pole of a magnet is always opposite to that on the north pole, it follows that the magnet will turn until its axis is perpendicular to the wire, unless some other force or forces prevent it.

If the wire be twisted into a coil, lines of force will pass round every element of the wire in the direction indicated above, and these passing all in the same direction through the coil it follows that—

If a current flow round a coil a north magnetic pole will tend to pass through the coil in the direction in which a right-handed screw would advance if rotating in the direction of the current.

Since the south pole of the magnet would tend to move in the opposite direction, it follows that a magnet suspended within a coil of wire will tend to turn so that its magnetic axis is perpendicular to the plane of the coil. This arrangement constitutes a galvanometer.

An astatic system is a mechanical system which has no definite position of equilibrium, but which will rest in any position in which it is placed, though free to move.

Two magnetic needles of equal magnetic moment rigidly connected so that their axes are parallel but their north poles point in opposite directions, constitute a system which is astatic as far as the earth's magnetic force is concerned, for whatever couple may be exerted by the earth upon one needle an equal and opposite couple is exerted upon the other. Such a pair of needles suspended so as to be free to turn in any direction would behave as though there were no magnetic force exerted by the earth.

Practically it is impossible to obtain two needles whose magnetic moments are *exactly* equal, and to connect them so that their axes are *exactly* parallel. If the axes were parallel but the moments unequal, the needles would set in the magnetic meridian, in obedience to that of greatest magnetic moment. If the magnetic moments were equal, but the axes not parallel, the needles would set so that the vertical plane bisecting the acute angle between the axes would be perpendicular to the magnetic meridian. When, as is the case in practice, the moments are not quite equal and the axes not quite parallel, the system takes up a position intermediate between those just mentioned. It is therefore not strictly astatic, but the couple exerted upon it by the earth's magnetism when the needles are deflected from their positions of rest is extremely small.

If two magnetic needles are suspended one above the other so as to form an astatic combination, and the lower needle is surrounded by a coil of wire through which a current can be sent, a very delicate "astatic" galvanometer may be formed. It will be seen that the current flowing through the upper portion of the coil will tend to turn both the needles in the same direction since their magnetic axes are parallel but reversed.

Sometimes a coil of wire surrounds each needle in an astatic galvanometer, and the current is then made to flow round the two coils in opposite directions.

When a current flows round the coil of a galvanometer, the needle of which is in equilibrium when parallel to the plane of the coil if no current is passing, the needle will be deflected through an angle which increases with the strength of the current. The needle will rest when the couple exerted upon it by the earth is equal and opposite to that exerted by the current. If the length of the needle be very small in comparison with the diameter of the innermost circle of wire in the coil the *tangent* of the angle of deflection will be proportional to the current, and inversely proportional to the horizontal intensity of the permanent magnetic field in which the needle swings. Hence, the sensibility of the instrument will be increased by diminishing the intensity of the permanent magnetic field. This is usually effected by means of a permanent controlling magnet which is turned so as to oppose the earth's action on the needle, and by causing this magnet to approach or recede from the needle the earth's action can be wholly or partially neutralised, and by properly turning the controlling magnet the galvanometer may be employed with its coils in other planes than the magnetic meridian. The manner in which the directive action of the earth has been overcome in the astatic galvanometer, so as to increase the sensibility of the instrument, has been already explained.

(To be continued.)

TESTING DYNAMO MACHINES.

BY JAS. SWINBURNE.

(Concluded from page 33.)

In some cases there may be a little difficulty in arranging cells to give very large currents. The two machines may then be run off as shown in Fig. 3. The pulleys are arranged so that the generator runs at its normal speed, and the motor runs slow enough for its *e* to be the same as the *e* of the generator. The loss in the system is not made up by supplementing the electromotive force of the generator, as in the last case, but by increasing the current in the armature of the motor. A small dynamo, D, giving, say, 110 volts, is arranged to excite the field-magnets of both the large machines, and to work into the motor armature in parallel with the generator.

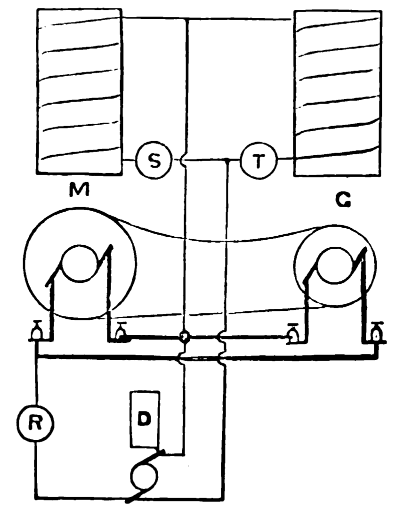

Fig. 3.

The current from D is regulated by the resistance till G is under normal conditions. The field and armature losses are taken in the usual way, and the stray power determined. To assess the stray power the belt slip may be first roughly deducted, and the remainder divided according to the power taken by each machine when run as a motor with no load, and with the same armature electromotive force as when under test. The real loss from belt slip can then be more accurately found, and the calculations made again. Instead of using pulleys of different diameter the field of M may be weakened, as in Dr. Hopkinson's method.

It is hardly necessary to go into the question of coupling up compound machines for the same tests, as the stray power is estimated in the same way, the only difference being some slight complications in the connections. The whole difficulty lies in the accurate determination of the stray power and in the accurate division of it into loss in the motor armature, loss by belt slip, and loss in the generator armature.

Fig. 4 shows two machines coupled to secondary batteries; the motor may be any machine of sufficient power to drive

Digitized by Google

the generator. This is the method used by Mr. Butler for testing motors, and it is virtually the same as Capt. Cardew's arrangement. To find the loss of power, the watts spent in M and those given back by G are taken, and the difference less the power spent on resistance gives the stray power. Each machine is then moted separately with no load, as already explained, and the stray power in each determined. This method and Captain Cardew's have the advantage that any machine that is large enough will do as a motor; but they have the disadvantage of needing three large machines or else two large machines and a lot of secondary cells. Captain Cardew's method also demands a resistance frame large enough to take the whole output of the generator.

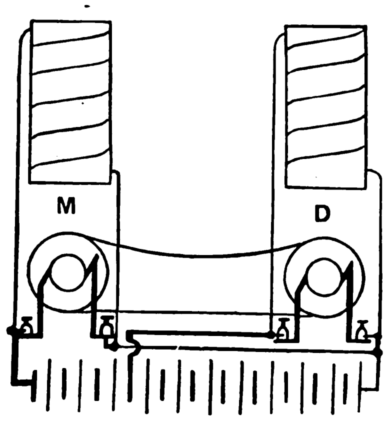

Fig. 4.

On the 7th of August last two machines, made by Messrs. Crompton and Co., for the War Department, were tested by Captain Cardew, according to his own method; the writer was fortunate enough to be there and witnessed the tests.

The particulars of the machines are as follows:—Armature resistance ·027 hot, field-magnet resistance 7·5 hot; both machines are shunt-wound, and their working conditions are 105 volts and 325 amperes at 450 revolutions. The two machines were coupled as shown in Fig. 5.

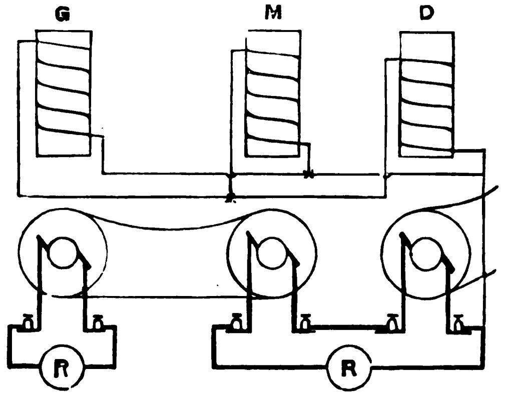

Fig. 5.

The motor M was driven from the third machine D, which was driven by an engine which is not shown in the figure. Both fields were excited direct by the dynamo D. The current through the armature of the motor M was increased gradually, so as to start it without short circuiting the dynamo D, and when the two machines had reached their full speed the generator G was made to work through a resistance frame.

Unfortunately this resistance was too small to take the load of the machines, so they had to be tested with 170 instead of 325 amperes.

The machines were also run below their normal speed. There were two reasons for this: in the first place the dynamo D could not well be driven fast enough to give 130 or 140 volts without putting on a different pulley and arranging a resistance in the shunt, and to drive the two machines so that the generator should go at its normal speed the motor would need about 20 per cent. above its normal terminal electromotive force, and about 10 per cent. more would have to be allowed for loss in the leads. In addition to this the field-magnets were excited with 128 volts instead of 105.

The readings were—

	Motor.		Generator.	
	Volts.	Amperes.	Volts.	Amperes.
	118	163	107·5	145
	117	162	106·5	145
	115	161	106·5	145
	114·8	158	105·5	142·3
Mean...	116·2	161	106·5	144·3
Speeds...	379		371	
	384		378	

the speed takers being changed over to eliminate personal errors. The fields were excited with 128 volts. Without deducting the stray power, we thus have

Power supplied to motor	18,710
Armature loss by resistance	700
Power at belt	18,010
Belt slip at 1·7 per cent	330
Given to generator	17,680
Armature loss by resistance	640
Calculated output	17,040
Actual	16,430
Stray power	610

The stray power so calculated is evidently much too small. On running the machines without any load on the generator 3,000 watts were absorbed. It is evident, therefore, that the readings, though accurate enough to serve to show the method, are not accurate enough to be taken as an example of testing. Moreover, the currents were too small, so the tests would only give the efficiency at half load. This is 86·5 for the generator. It appears probable that the machines can be tested with sufficient accuracy for all practical purposes, and perhaps more accurately than by any of the above methods, in the following way:—The machine to be tested is moted with no load, and with the field so excited that it gives the normal armature electromotive force at the normal speed. The armature volts and amperes are taken, and the product is the stray power or loss of conversion. By taking the resistance hot of the armature and fields the commercial efficiency can be calculated. Messrs. Crompton and Co. have lately made some tests to determine the efficiency of a little slow speed machine for Sir David Salomons. Some other tests were taken at the same time. The particulars of these would take up too much room, but it appears certain that the power taken to turn the machines at no load added to the loss by resistance at full load is equal to the whole loss at full load. The machines tested were very small, and at no load the readings did not always agree well. The machines took much less power when the belt was off. The discrepancies would probably hardly be noticed in large machines. With the little machines tested they were sometimes 3 per cent. or so. Taking this method of testing as correct, we may calculate the efficiency of the Crompton machines for the War Department already mentioned as follows. The two machines, separately excited, take 113 volts, and 30·5 amperes, in the motor armature. This gives 3,450 watts for the two, or 1,725 for one. The losses are then:—

Stray power	1,725
Armature resistance (hot)	3,350
Shunt (hot)	1,600
Total loss	6,675
Output	35,800
Belt power	42,475

Commercial efficiency at full load, 84·4 per cent.

Digitized by Google

There are two points to be noticed here. One is that as the fields were very strongly excited the stray power was probably too high. The other is the very low electrical efficiency of a slow speed machine. Advocates of slow speed dynamos do not seem to realise this. A machine run at half speed has the same electrical loss, but less than half the output, so that machines like these under discussion give a low electrical efficiency because they run slow. At double the speed, they would either give a larger output or would give the same output at about 96 per cent. efficiency. It is doubtful, therefore, whether it is a good plan to use a slow speed machine at all when driven by a belt. The same type of machine driven at 700 revolutions gives an output of 110 volts, and 500 amperes at an electrical efficiency of 93·2 per cent. The practice of running slow-speed machines is strongly to be condemned. A machine running at half speed needs to be twice the size; and even then has twice the percentage of loss. It would be interesting to calculate the efficiency of the Edison-Hopkinson machines by this method. The power supplied to the two machines separately excited at no load, is, according to *The Electrician* for March 12th, 1886, 7·169 horse-power, or 5,350 watts, say 2,675 per machine. We thus have, for the generator:—

Stray power	2,675
Loss in armature	1,360
Loss in magnets	716
Total loss	4,751
Output	40,600
Power supplied by belt	45,351

Commercial efficiency, 88·2 per cent.

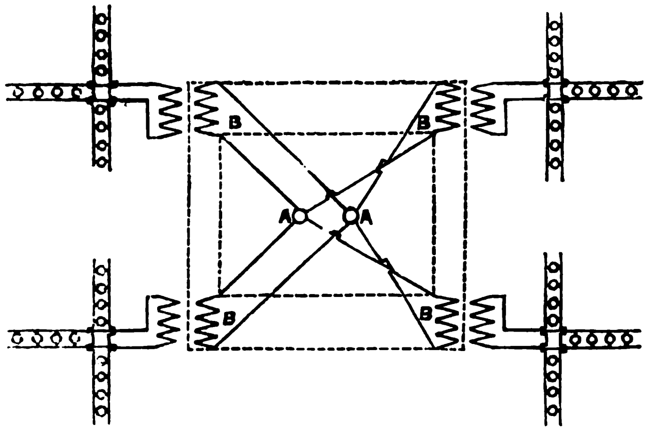
This determination does not agree with those of Drs. Hopkinson. They make out the commercial efficiency of the dynamo to be 93·23 per cent. Unfortunately the published tests of Drs. Hopkinson discrepe too much to be of use. The power spent on turning the armatures with no current is given as 7·169 horse-power, and when the full current is taken it apparently drops down to 2·22. The 93·23 per cent. is calculated from the latter figure; but what becomes of the odd, the very odd, 5 horse-power? It would be very interesting to know what electrical power it takes to drive one of these machines empty.

The accuracy with which dynamos can now be tested—thanks to Dr. Hopkinson—will allow them to be used instead of Prony brakes; and instead of the dynamometer being used to measure the power of a dynamo, we may hope to see the dynamo and motor take the place of the transmission dynamometer.

DISTRIBUTION BY TRANSFORMERS.

We learn from the *Æsterreichisch-ungarisches Patentblatt* that Messrs. Siemens and Halske propose to effect the distribution of electricity from central stations by subdividing the area to be supplied into several smaller districts, and distributing electricity in parallel mains in each such sub-district by means of large transformers, which are themselves to be supplied with current from the central station. In the publication from which we obtain these details Messrs. Siemens and Halske set forth the disadvantages attending the employment of transformers upon parallel circuits, such as the amount of copper which is required for the mains (since the potential must be kept constant and equal at every transformer on the circuit, irrespective both of the number of lamps and of transformers in use), and also the objection of bringing into the consumer's premises very nearly the full tension of the dynamo. They then refer to the difficulties connected with the regulation of transformers when connected in series, for which no solution has yet been made known, and finally they explain a method of connection by which it is proposed to obtain perfect regulation without incurring the difficulties of the parallel system. The connections proposed are shown in the accompanying figure, where A A are the terminals of the alternating current machines at the central station. Any required number of machines joined in parallel may be employed. From these points mains are carried direct to the terminals of the primary coils of the transformers (*b*) in each sub-district, and the latter are again joined in parallel by additional sub-mains, as shown by dotted lines.

Although we believe that the plan of using transformers as sub-centres of distributions is good and practical (though even this was, perhaps, scarcely thought of first in Berlin), yet as to the arrangement of the circuits it is certainly neither more nor less than a connection in parallel combined with a system of feeders such as were first employed by Edison. By splitting up the main current, a saving of copper over that required for a single parallel going all round the circuit is of course effected, but it is very doubtful whether, in any given case, this economy would not disappear by the time that the sub-mains between the several district have been provided for.*



Our chief objection, however, to the scheme, so far as it has any pretension to be considered as a step towards a general and final solution of the problem, arises from the fact that it is essentially a *central* station system. Not only must the central station be centrally situated in order to secure economy, but the transformers must also be placed in the centres of their sub-districts. From this point of view it is almost to be considered a retrograde step, for one of the chief advantages to be gained by the use of transformers arises from the facility with which, if they could but be employed on series circuits, ex-central distributing stations are immediately available. The importance of any system which admits of the use of high tension currents in a system of general distribution, so as to enable the machine to be placed upon the outskirts of the area to be supplied, is fully appreciated, but this the scheme of Messrs. Siemens and Halske does not effect.

* The authors state that the dimensions of the sub-mains will be so taken as to provide an adjustment for all ordinary discrepancies between the rates of consumption in different districts. In order to provide against *extraordinary* departures from the normal balance, they contemplate the introduction, when necessary, of resistances in the circuit of the main leads of those transformers which are doing minimum work. But it appears to us that the whole of this part of the scheme is based, to some extent, upon a misconception. In giving an illustration of the supposed action it is stated in so many words that if the potential at the machines remains constant, then the current in the main lead belonging to any given transformer tends to *increase* when the number of lamps in the secondary circuit of that transformer is ***diminished***. It is, however, tolerably well known (and it may readily be proved by theory) that the reverse is really the case. An easily-remembered rule of thumb clue to the elementary conditions of transformer circuits may be given by stating that *the virtual resistance of the primary coil varies in the same direction as the actual resistance of the secondary.* Consequently, when lamps are turned off the actual resistance of the primary is increased, and under constant difference of potential the current through the coil diminishes (instead of increasing, as stated by Messrs. Siemens and Halske). Owing to the loss of potential in the mains this decrease of current tends to cause a slight rise of potential at the terminals of the primary; but in the system under consideration this is to some extent counter-balanced by the fact that the presence of the sub-mains diverts into this route a portion of the current passing through the other primary coils. The proportion of current so diverted obviously depends solely upon the relative resistances of the various mains and sub-mains. To secure perfect compensation in this way, it is necessary that the resistance of all the mains be equal to one another, while the resistance of the sub-mains ought to be a vanishing quantity (!) In fact, as above intimated, the particular connections described have nothing to do with transformers *qua* transformers, but resolve themselves into a system of parallel mains with feeders by which the difference of potential may be kept approximately uniform at all points.

CORRESPONDENCE.

THE PRESIDENT OF THE SOCIETY OF TELEGRAPH-ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I see that in the last number of *The Electrician* you raise the question as to who is the right man to fill the post of President of the Society of Telegraph-Engineers and Electricians in the coming year, the Jubilee of the Queen, and, as you remark, of the Electric Telegraph. You justly say that this Society ought to take the leading part in any organised effort to commemorate the Telegraph Jubilee; that they should select a president who will not only represent it with dignity, but conduct its affairs with energy and discretion; that the choice should lead to no heartburnings or humiliations, falling upon a man above the suspicion of rivalry and outside the range of jealousy.

I have nothing to say about the name you suggest, but it surprises me that you do not notice the claims of the man who by a most fortunate coincidence comes in the natural rotation. You must surely be aware that the senior vice-president of the Society was the first practising telegraph engineer in the world; that he was a pupil of Sir William Fothergill Cooke; that he is now the *doyen* of the engineers to the old telegraph companies; that he commenced his submarine experience in 1853 by laying a cable between Scotland and Ireland; that in this and the next year he laid a greater length of underground lines than has ever been laid since, besides over ten thousand miles of overground wire; that he first used a sounder as a receiving instrument, and introduced numerous improvements into the practice of telegraphy. The senior vice-president was one of the projectors of the first Atlantic cable; he was its engineer, with Mr. Cyrus Field as manager. He laid the first cables to India and in Central and South America. It was he who, with Mr. L. Clarke, in 1861, led the British Association to deal with electrical standards. His name figures in the first list of members of the Society of Telegraph-Engineers. He was a British Commissioner at the Paris Electrical Exhibition in 1881. He has served his country as a Member of Parliament. He was knighted by the Queen, and afterwards declined the offer of a baronetcy. He has nothing to gain by being president of the Society, except that deserving recognition of a useful life which confers more honour on the Society than on the individual.

The man with this splendid record is Sir Charles Tilsden Bright. By his election the Society will be represented with dignity and discretion. The choice, to use your own words, can lead to no heartburnings or humiliations, falling upon a man above the suspicion of rivalry and outside the range of jealously.—Yours, &c., GEORGE FORBES.

34, Great George-street, Westminster, December, 1886.

NOTATION, SATURATION, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I do not wish to continue a controversy unnecessarily; but in this case there are practical questions of importance at issue, and I think it desirable to say a few words more on them. As to the units. The objects of all our language, numerical and other, are to be intelligible and to avoid the risk of mistake. I maintain that the C.-G.-S. system, as used among those who write papers and read them, is the only system now in use which fulfils these requirements. The two objections to such a unit as C.-G.-S. induction per square inch are—First, that the numbers obtained are unintelligible until a process of reduction has been gone through. And this is illustrated by the fact that Mr. Kapp's own comparison of his own numbers with others appears to have led him to erroneous conclusions, as the statements he made as to the comparison could not be justified. Secondly, that it mixes up two different units in two parts of the same investigation. And surely all experience teaches that this is a method well calculated to lead to mistake. If, Sir, you wish to see C.-G.-S. abolished, there is the old English foot grain second system only lately disused. But do you really think that it is ever likely to be either so intelligible as the universal language of C.-G.-S., or so free from liability to mistake?

It is quite unnecessary to use grammes or centimetres in the workshop if you do not like them, though I have never experienced any difficulty. We speak freely in my small shop of such quantities as 10 or 20 thousand of magnetic induction, and we do not find the unit inconvenient. But that is a different question from this, of adopting mixed units in the statement of results.

Mr. Kapp's rule for the area of wire in a wound armature seems to me to be wrong, though I did not expect an error of that kind. The errors I alluded to would arise more from the impossibility of securing any accurate geometrical arrangement, or of preventing changes of figure in the section of the wire due to the force used. But the error of the rule is so serious that I append what I suppose to be the correct rule, assuming that these difficulties are neglected. Mr. Kapp's rule assumes that the layers lie on each other, as shown in Fig. 1; but that is not so. When wire is wound, the coils of each layer bed in

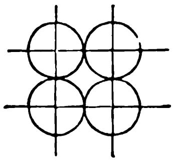

FIG. 1.

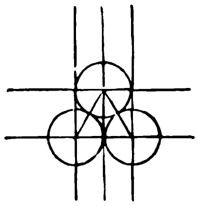

FIG. 2.

the hollows of the layer below, as shown in Fig. 2. The calculation shows that the 23,150 represented by Mr. Kapp's "25 lines" would be reduced to 20,135 by this correction. This certainly agrees well with his disc value, 20,460. But, on the whole, I am disposed to suspend my judgment as to all these values, in the absence of an account of the whole process employed.—Yours, &c.,

R. H. M. BOSANQUET.

Layers.

Distance between lines of centres of layers .... = altitude of triangle, Fig 2.
$= 2r\sin 60^\circ$
$= r\sqrt{3}$

Depth of n layers .... $= nr\sqrt{3}$ nearly.

Length of layer, m wires ...... $= 2mr$.

Section through axis of coil.

Total area occupied by mn wires $= 2\sqrt{3}\,mnr^2$

Wire area .... $= \pi mnr^2$

$$\therefore \frac{\text{Total area}}{\text{wire area}} = \frac{2\sqrt{3}}{\pi}$$

instead of $\frac{4}{\pi}$ according to Mr. Kapp; $\therefore$ the wire area, as estimated by him, is too small in the ratio $\sqrt{3} : 2$, and the estimated induction in the wire area is too large in the same proportion.

Then (having recourse to logarithms, though despised by Mr. Kapp)

$$\log\sqrt{3} = \cdot 23856$$
$$\log 2 = \cdot 30103$$

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The passage in Mr. Kapp's letter to you of last week following his graceful acknowledgement of the justice of Mr. Bosanquet's claim to priority in the matter of the "theory of

Digitized by Google

magnetic circuits" is of a nature to invite comment. Mr. Kapp asks "why he did not apply his investigations to the practical purpose of teaching us how to design dynamo machines?" and following this are some remarks which read as if, in their author's opinion, scientific research for the mere sake of advancing knowledge was of very secondary importance. It is difficult to believe that Mr. Kapp intended them to bear this construction, but if he did not, his choice of words is unfortunate.

It may be permissible to draw Mr. Kapp's attention to the following quotation from the works of one who is admittedly the *beau ideal* of an experimental investigator, and to Prof. S. P. Thompson's remarks thereupon:—"I have rather, however, been desirous of discovering new facts and new relations dependent on magneto-electric induction than of exalting the force of those already obtained, *being assured that the latter would find their full development hereafter*" (Faraday, "Exp. Res.," § 157). The italics are now added. Concerning this passage from Faraday, Prof. Silvanus Thompson says:—"Can any passage be found in the whole range of science more profoundly prophetic, or more characteristically philosophic than these words, with which Faraday closes this section of his researches (see "Dynamo Electric Machinery," 2nd Ed. p. 224).

With such an example before him, it is scarcely to be supposed that Mr. Bosanquet will regret leaving the practical application of his discoveries to others, notwithstanding that had he done otherwise Mr. Kapp and his professional colleagues "would have been extremely grateful." Surely it is a mistake that any man naturally adapted for experimental research should devote even a part of his time to work that can be readily done by others, and, as will be generally admitted, that where there is one capable of really good experimental work, there are *twelve* who can well apply the results of such research to the good of mankind.—Yours, &c.,

99, Bishop-street, Manchester. ROBERT B. POLLITT.

THE CABLE SYSTEM.

The following letter, and the article upon it, appear in the current number of *Imperial Federation*:—

CRUISERS OR CABLES, OR BOTH?

To the Editor of IMPERIAL FEDERATION.

SIR: In your issue of November 1st there is an article entitled "Only Once in Six Years," and much is made of the terrible importance of even a few minutes' interruption of telegraphic communication at a time when war is apprehended or even during a "Russian scare."

This article, in common with many others in the daily press at this time of active company promotion, deals with the subject as if a remedy could be found, and cables laid somewhere where they could not be cut.

I ask permission to state in your columns that to entertain such an idea is to live in a fools' paradise. All cables can be cut, no matter what their length or how deep the ocean may be.

Submarine cables should be looked upon as laid for commercial purposes in the main and only incidentally for war purposes, which is the abnormal condition of great nations possessing fleets.

It is not probable they would be cut prior to a declaration of war, which no doubt would be apprehended in time for the colonies and merchants to arrange their plans for such a contingency; and our rulers should be trusted to foresee the probable contingencies and be prepared with such a plan for the concentration or disposition of their land and sea forces as could be supported by cruisers and despatch vessels, or, if need be, act without such support.

I venture to say that cables, colonies, and commerce must all take care of themselves as they best can at the commencement of any war in which this country is likely to be involved with any Power possessing cruisers until we shall have established supremacy at sea.

Is not this obvious?

Neither cables nor commerce can be guarded without cruisers, and if thousands of miles of cable are laid across broad oceans seldom traversed by our mercantile marine, is it to be expected that a fleet of armed cruisers can be told off to guard cables which can be cut any night at any number of places the enemy may select?

Both cruisers and repairing steamers watching or working in the middle of broad oceans would soon exhaust their coal supply and would always be far away from a coaling station.

If cables are to be of use in time of war for commercial purposes they must be laid along the track where our fleet and cruisers are most likely to be concentrated to guard our transports, store ships, and communications, as near the track as possible of our coaling stations and arsenals and the rendezvous of our ironclads.

Repairing steamers and large supplies of cable must be stored along these routes when war seems imminent.

It is certain that in a great war cable ships will accompany the fleet with cable for strategical purposes. Then with despatch boats and repairing ships communication will be established as soon as possible, and as soon as it is safe for our commercial marine to go freely to and fro it will be equally safe to repair cables.

What is required is more cruisers rather than more cables; but it is not to be expected that a sufficient number of cruisers will ever be available to guard cables laid across great oceans merely because they can be called, in time of peace, alternate lines.

In the interest of Federation and of commerce it is of infinitely greater value to have cheap telegraphy by lines which can be the most easily protected than to multiply lines at the expense of the tax-payers which serve no purpose other than that of ruinous competition.

My conviction is that submarine cables should only be laid in short sections, touching at as many points as possible likely to develop commerce and be of use to the world. When war is imminent the necessary provision must be made at any cost. To try and anticipate this is a waste of public money.—I am, Sir, your obedient servant, JAMES ANDERSON.

50, Old Broad-street, London, E.C., 5th November, 1886.

SHOULD A BOW HAVE ONE STRING OR TWO?

Sir James Anderson's remarks upon cable cutting, in our correspondence columns, will be read with interest as coming from a distinguished expert. "More cruisers rather than more cables" is the advice he gives. We should like to accept the one without excluding the other. With the commercial aspect of the question we are not now concerning ourselves; whether duplicate cables would really promote ruinous competition at the expense of the taxpayers does not fall within the scope of our inquiry. What we have to consider is, whether the defence of the Empire would or would not be assisted by an ocean cable route to Australia.

Sir James Anderson admits that, if war broke out to-morrow with a naval power, cables, colonies, and commerce must all take care of themselves. He means, we suppose, that cables might be cut, colonial cities shelled, and commerce smashed, the last two resulting from the first of the trio. If, however, cables remained intact, we do not imagine Sir James Anderson would deny that both colonies and commerce would have such timely notice as to enable them to mine their harbours, lay up their shipping, and man their defences. The telegraph annihilates distance and renders a surprise impossible. But cables, it is stated, can be cut, no matter what their length or how deep the ocean may be. To this we reply, that you must first find your cable before you can cut it; that to find it is much easier when the sections are short, and the charts obtainable at various stations on non-British, possible hostile territory; that, in any case, it is easier to find and to cut one cable than two; and that on the broad ocean between, say, Vancouver and Sydney, the enemy's cruiser would be further from his base and running a greater risk than is habitual with foreign vessels, when war with England is imminent. It is one thing to slip out into the Mediterranean from Toulon, or Spezia, or the Black Sea, but a very different matter to reach the Ocean cable route on the Pacific, even from Vladivostok.

After all, from the concluding sentence in Sir James Anderson's letter, we are inclined to think he differs from us only as to when the new cable route should be laid down, though in that *when* there is a mighty virtue! "When war is imminent, the necessary provision must be made at any cost; to try and anticipate this is a waste of public money." We are quite content to have the issue raised on this question of the right time, and to leave the public to decide. We advocate having two strings to our bow, so that when war is imminent we may be ready for it. Sir James Anderson wishes to wait until the last moment, and then make *the necessary provision* at any cost. But it is not long since the country had a terrible lesson, which taught that the utmost endeavour and the most lavish expenditure cannot work impossibilities, and that a moment comes when the cry goes up "Too late!" We urge such moderate and prompt expenditure of public money as may be required to subsidise an alternative ocean cable, and thus enable *the necessary provision* to be made while yet there is time.

SOCIETY OF TELEGRAPH-ENGINEERS.—Notwithstanding that our present issue contains eight extra pages, we regret that the pressure on our space compels us to leave over until next week our report of last night's meeting of this Society.

A letter awaits A. D.

REDUCTION OF CAPITAL *AND* DIVIDEND.

Ever since the Act of 1867 conferring on a Limited company the power to modify its Memorandum of Association there has been very little doubt as to the legality of reducing capital by special resolution of the shareholders, but it has never been suspected until now that this power extended to interest or dividend which had been definitely fixed in respect to preferential shares. Nominally, this cannot be done; but practically it can, as has just been ruled by the Court of Appeal in the case of the DIRECT SPANISH TELEGRAPH COMPANY *ats* BANNATYNE, reported in these columns last week. The judgment delivered by Lords Justices COTTON and FRY, reversing the decision of Vice-Chancellor BACON on the first hearing of the case, is of considerable importance to the mercantile world, and we are surprised that it has attracted so little attention in that portion of the Press which devotes itself specially to financial and commercial matters. To Electric Lighting companies, at a not far distant time, the subject may be of some moment; and to most of the Submarine Cable companies it is one of no small interest even now. The position of the DIRECT SPANISH TELEGRAPH COMPANY is unprecedented in some respects; but in its main features a similar contingency may arise any day with other cable companies, and the question will naturally occur to their respective shareholders, ordinary and preferential, How do we stand now that Mr. BANNATYNE'S claims have been decisively rejected on appeal?

Briefly stated, Mr. BANNATYNE, on the part of himself and the preferential shareholders in the DIRECT SPANISH TELEGRAPH COMPANY'S cables, contended that they were exempted by reason of their preferential position from the effects of a reduction of capital formally agreed upon by the majority of the proprietors and Directors of the Company. One of its two cables was lost; consequently, half its capital was dead and buried at the bottom of the sea. In these circumstances it was resolved to reduce the nominal capital to the dimensions to which misadventure had reduced the actual capital, namely, by one-half. Unhappily, there is nothing exceptional in that part of the proceedings, and it was submitted to, as sensible men of business have done before and since. But £60,000 of the capital consisted of preference shares, bearing a fixed interest at the rate of 10 per cent. per annum; and the fortunate holders of these shares, while assenting to a reduction which they had no power to prevent, not unnaturally demurred to the reduction of the preferential capital; or, more accurately, to the reduction of the 10 per cent. interest stipulated for when the preference shares were issued. We say not unnaturally, because we believe that ninety-nine people out of every hundred would suppose that the very essence of a preferential interest in such bargains as these is that it is unaffected by the risks to which an ordinary interest is liable. The contrary assumption seems to deprive the term "preference" of any meaning; and might lead to all sorts of fraudulent evasions and breaches of faith. It was partly, we believe, on the latter ground that Vice-Chancellor BACON gave judgment in favour of the preference shareholders, a decision the other way being liable to great abuse in general application, whatever might be the merits of the particular case then before him.

On more careful review of the particular case, however, the judges of Appeal have overruled the first decision, and emphatically upheld the action of the Directors, who had included the preferential capital in the general reduction. The dismissal of the original action against the company with costs will be startling news to holders of preferential stock; but on a candid examination of the facts it will be seen that substantial justice has been done. The Acts on which the preference shareholders relied are merely declaratory and permissive; and the Courts have always a discretionary power to take into account the precise reason and object of any capital reduction which one set of shareholders may approve and another set disapprove. If, said Lord Justice COTTON, it were done not honestly for the purpose of reducing capital, but for some indirect other purpose, then a question might be raised; if, on the other hand, the judge is satisfied that the creditors are duly protected, "he may," in the words of the Act 1867, "make an order confirming the reduction on such terms and subject to such conditions as he deems fit." In the present case no question could be raised as to the *bona fides* of the Directors, who simply acted in conformity with the powers granted under the Articles of Association, which were in force when the preference shares were issued, and with which the preference shareholders must be presumed to have been acquainted when they invested their money. Section 10 of those Articles empowered that reduction, and the only question remaining was whether the bargain entered into with the preference shareholders had been kept. Admitting that what had since happened was not contemplated when the bargain was made, still the bargain itself cannot be invalidated on that account, unless its terms did not cover what has unexpectedly happened.

Digitized by Google

Now, the bargain was made by two parties, the one consenting to invest its money at a fixed rate of interest, the other consenting to receive it, but subject to its Articles of Association. These Articles, as already stated, empowered the borrowers to reduce their capital, if occasion required such a course; and the Court of Appeal has ruled that the capital invested under preferential conditions later on was subject to this contingency. No power exists, however, to reduce the preference dividend; and the sanctity of the bargain is preserved by maintaining the right to the 10 per cent. dividend originally agreed upon. In other words, the capital of preferential shareholders may be reduced like ordinary capital, but the interest may not. Owners of preference stock in the DIRECT SPANISH Cable Company will get their former rate of interest, but it will be on only half their investment. This is the net upshot of the present lawsuit; and although it is hard upon the original plaintiffs in this particular case, a ruling of an opposite kind would have been still harder upon the much more numerous body of ordinary shareholders, who otherwise might incur all the risks of an undertaking, and be compelled to deprive themselves not only of all dividends but of all their capital in order to pay a perpetual annuity, whatever happens, to the proprietors of preferential shares. "When," said one of the judges, "the resolutions reducing the capital of this company are carried into effect, the bargain, in my opinion, will be performed by giving the holders of those preference shares 10 per cent. on the then amount of their capital in the company." We should imagine that the delivery of this judgment has caused considerable flutter in the camp of preferential shareholders whose money is invested in undertakings liable to have their capital "reduced."

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS' PRESIDENTIAL ELECTION.

Some remarks of ours in last week's *Electrician* relating to the forthcoming election of president for the above Society seem to have been misunderstood. In the first place we studiously avoided making any definite recommendation on a point which, after all, finally rested with the Council; and in naming a particular person we did so, as we explicitly stated, merely by way of illustrating the possibility of finding a candidate free from most of the objections to which we made reference. It was perfectly well known that the Council up to that time had not been unanimous in their views as to next year's presidency; and our object was to suggest a course by which unanimity might be arrived at. Other courses were open; the Council might have re-elected the present president, or once more called to the chair a past president in the person of Sir W. Thomson, providing—which is by no means certain—either of these gentlemen would have consented, in the particular circumstances, to be put in nomination. It is hinted that if the Council's nominee is rejected the Council might resign. This would be an act unworthy of the Council, inasmuch as its duty, so far as the election of officers is concerned, is to advise the members rather than to dictate to them. The members are surely able to judge as to who can or who can not, in their estimation, worthily fill the office of President. The best interests of the Society are usually served by members loyally supporting the Council in the choice it makes; but *our* duty to our readers, to the profession, and to the Society is unmistakable, and it is to give expression to any such differences of opinion as have arisen in the Council, and which undoubtedly prevail among a large section of the members outside the Council. The members must then use their own judgment in the selection of a suitable candidate. We have attempted merely to give publicity to facts as they have been urged upon us. Unfortunately, the Council is not consistent in the question of rotation, or we should not be asked to support Mr. Crookes as a vice-president. Do not let us be misunderstood; we have nothing to say against Mr. Crookes, who is an eminent chemist, but in this case the Council has put aside Mr. Ansell, an old telegraphist—the senior member of the Council—to make room for Mr. Crookes. If the members are to be consistent, and support the claims of seniority, then we ought to have been told to vote for Mr. Ansell and not for Mr. Crookes. We believe we are acting in the interests of the Society by discussing the subject, the other side of which is ably treated in a communication from Prof. G. Forbes in another column.

BRITISH ASSOCIATION, 1886.

The following papers marked * were contributed to the late meeting of the British Association on various subjects connected with Electrolysis.

SUR LA CONDUCTIBILITE ELECTRIQUE DES DISSOLUTIONS SALINES TRES ETENDUES.*

By M. E. BOUTY. Abstract by OLIVER LODGE.

(*Concluded from page 63*).

IV.—*On the Migration of Ions and its Relation with the Conductivity of Salt Solutions.*

The author styles the case when the migration number of each iron is simply ½ as "normal electrolysis," and he quotes results of Hittorf to show that the salts which thus behave are anhydrous salts, *e.g.*, AmCl, KCy, KCl, K_2SO_4, K_2CrO_4, KNO_3, KBr, $KClO_3$, $KClO_4$, Ag_2SO_4, KI, $AgNO_3$.

For all these Hittorf's number (n) is very near ·5, and scarcely varies with dilution. But for salts which definitely combine with water neither of these statements holds. Here are Hittorf's numbers. S represents the weight of water combined with 1 gramme of the salt; n expresses the loss of concentration at the cathode while 1 equivalent of electrolyte is decomposed.

Salt.	S	n	Salt.	S	n
$CaCl_2$ …………	1·6974	·780	$BaCl_2+2H_2O$..	3 5	·662
	2·0683	·771		8·4	·642
	2·3608	·765		100	·614
	2 739	·749	$MgSO_4+7H_2O$..	5·3	·762
	3·9494	·727		309·6	·656
	20 918	·683	$CuSo_4+5H_2O$...	6·35	·724
	138·26	·673		9·56	·712
	229·2	·683		18·08	·675
$MnCl_2+4H_2O$..	3 306	·758		39 67	·645
	190·41	·682		148·3	
$MgCl_2+0H_2O$...	2·48	·806	$ZNSO_4+7H_2O$.	2·524	·778
	3 7	·778		4·052	·760
	22·2	·706		267·16	·636
	128·3	677	$Na_2SO_4+10H_2O$	11·77	·641
	241·3	·678		50 65	·634

It seems from this table that hydrated salts approach normality as their solutions become very dilute. They then also tend to obey the law of equivalents (k/m = const.); so the two things are connected.

"When a salt obeys the law of equivalents, its electrolysis is normal (migration number ½); when it does not obey it is abnormal, and the divergence which the law presents to the law of equivalents is so much the greater as the number n differs more from the normal value ·5. . . . There is thus, between the resistance of salt solutions and the phenomenon of migration, a very close relation, impossible to overlook."

A still more striking proof of this relation is afforded by

Digitized by Google

some salts of which the electrolysis is not normal and does not tend to become so with increasing dilution. For instance nitrate of soda :—

	S.	n.
$NaNO_3$	2·066	·588
	2·994	·600
	34·76	·614
	128·7	·614

[The meaning of $n = ·614$ is that when an equivalent of of $NaNO_3$ is decomposed, ·614 of an equivalent is lost from neighbourhood of cathode and ·386 from neighbourhood of anode.]

The number n thus varies little with dilution, and appears rather to diverge from the normal value ·5 as dilution increases.

A comparison between $NaNO_3$ and KCl of the same concentration has furnished me with the following results :—

Concentration.	Ratio of Resist.	Ratio of Equivalents.
$\frac{1}{200}$	1·489	1·141
$\frac{1}{1000}$	1·476	

The specific resistance thus scarcely varies with dilution, and it is almost 1·3 time its theoretical value. The permanent anomaly of its electrolysis corresponds to a permanent disobedience of the law of equivalents. Salts which behave something like nitrate of soda are LiCl, NaCl, $CaSO_4$, $NaNO_3$, $NoClO_3$, $Ba2NO_3$, CaI, $Ba2ClO_3$; $Li_2SO_4 + H_2O$, $Ca2NO_3$, $+ 4H_2O$, $SrCl_2 + 6H_2O$, $NaI + 2H_2O$.

V.—*Discussion of the Results of M. Kohlrausch.*

Kohlrausch attributes to every ion a specific molecular conductivity which it preserves in every combination.

Bouty asserts that the molecular conductivity of all neutral salts in every dilute solution is the same ; and would thus consider that all the numbers of ionic velocity given by Kohlrausch should be all equal, which they by no means are.

He proceeds to criticise Kohlrausch's experiments by saying that the solutions he used were too concentrated, the weakest containing 5 per cent. of salt, while Bouty's went as low as ·025 per cent.

On the other hand Kohlrausch's tables are too comprehensive ; they include, first, acids and taric hydrates ; second, salts decomposed by water, double salts, &c.; third, neutral salts, which remain abnormal even in very dilute solution, or "abnormal salts."

The class of bodies most favourable to M. Kohlrausch's results are those relating to anhydrous and nearly "normal" salts. Here are his numbers for the following ions. The numbers for Am, K, Cy, Cl, Br, I, and NO_3 differ very little from a mean value 50. But for Ag, SO_4, ClO_3 the atomic conductivity is 40, and for CO_3 it is 36.

"To compare these numbers with my own, this is what I have done. Consider, for example, K_2SO_4 ; its molecular resistance according to Kohlrausch is

$$\frac{1}{48} + \frac{1}{40} = \frac{88}{1920}.$$

That of KCl, which I have used as a standard, is

$$\frac{1}{48} + \frac{1}{49} = \frac{97}{2352}.$$

The ratio of these is 1·1114.*

I have measured this sameratio at different concentrations—viz., $\frac{1}{20}, \frac{1}{200}, \frac{1}{1000}, \frac{1}{4000}$, and find numbers which, divided by the ratio of equivalents, give respectively

1·288 1·144 1·074 1·011.

These evidently tend towards the limit 1, and not to the number 1·1114 proposed by M. Kohlrausch.

Similarily with K_2CO_3 and $AgNO_3$.

For sulphate of silver compared with KCl, Kohlrausch's table would give 1·21, which I find by experiment ·981.

* This is a mistake. The velocity numbers themselves must be added, not their reciprocals ; so for K_2SO_4 $48 + 40 = 88$ is the conductivity, and for KCl it is 97 ; hence the ratio is 1·10. The difference being so small I have left the figures of M. Bouty unchanged, especially as the ground of his arguments is only partially affected, not removed. In a note to the September, 1886, *Journal de Physique*, p. 428, M. Bouty admits his slip.

These divergencies are not enormous, but they get much bigger if one proceeds to study normal hydrated salts whose conductivity varies so rapidly with dilution.

Kohlrausch's numbers for the following metals are very different from 50 :—

Ca 26
Ba 29
Cu 29 and 12
Mg 23 and 14
Zn — and 12

When two coefficients are given, the former belongs to ordinary salts, the other to sulphates, which otherwise M. Kohlrausch cannot get to obey his law.

Comparing these with KCl in the manner already explained, M. Bouty gets the following table, in which Kohlrausch's numbers are also inserted for comparison :—

Concentration.	$\frac{1}{20}$	$\frac{1}{200}$	$\frac{1}{1000}$	$\frac{1}{4000}$	Limit according to Kohlrausch.	
					As given by Bouty.	Corrected by O. L.
$CaCl_2$	1·437	1·339	1·251	1·181	1·428	1·29
$MgCl_2 + 6H_2O$ ...	1·339	1·277	1·131	1·029	1·549	1·34
$BaCl_2 + 2H_2O$ ...	1·290	1·133	1·081	·951	1·331	1·24
$Mg2NO_3 + 6H_2O$	—	1·323	1·249	1·163	1·581	1·4
$Cu2NO_3 + 6H_2O$	1·474	1·281	1·253	1·135	1·363	1·29
$MgSO_4 + 7H_2O$...	2·777	1·879	—	1·249	2·834	1·80
$CuSO_4 + 5H_2O$ ...	3·130	2·272	1·591	1·310	3·123	1·86
$ZnSO_4 + 7H_2O$ ...	2·924	1·923	—	1·220	3·123	1·86

"It suffices to read the numbers in any horizontal row to see that they tend towards the limit 1, not towards variable limits according to the nature of the salt. The ratios deduced from the table of Kohlrausch agree very nearly with the numbers in my first column for concentration $\frac{1}{20}$." Polarisation is so strong at the contact of metals with salts of Mg and Al that perhaps polarisation was not altogether avoided by Kohlrausch for the case of the magnesium salts above.

"To sum up: Molecular conductivities tend visibly to equality for hydrated as well as for anhydrous salts, and the disagreement of my results with those of Kohlrausch finds itself explained in the most satisfactory manner."

VI.—*Application of Faraday's Law to the Study of the Conductivity of Salt-solutions.*

"The law which I have just announced may be extended to a variety of salts. It suffices to know the manner in which the salt is electrolysed, and what quantity of salt is equivalent to KCl, for the application of Faraday's law."

The author then gives figures for various salts, classifying them thus :

a. Salts with several equivalents of acid.
b. Double salts decomposed by water (including alums).
c. Simple salts decomposed by water (tin salts and Fe_2Cl_6).
d. Stable double normal salts (K_4FeCy_6, &c.)
e. Double abnormal salts.
f. Phosphates and arseniates.
g. Bicarbonates.
h. Mercuric salts.
i. Tartar emetic and a couple of cobalt compounds.

He finds that $HgCl_2$, $HgBr_2$, and $HgCy_2$ are unique ; they are insulators. Water containing 5 grammes of one of these substances to the litre conducts very little better than pure water : 200 times less than what the k/m law would give. Sal alembroth, however, conducts.

VII.—*Organic Substances.*

Organic salts differ in no essential character from salts of which the acid and base are mineral. If the electrolysis is normal the law of equivalents rigorously applies, otherwise it does not, just as with mineral salts.

Bodies like alcohol, glycerine, glucose, urea, &c., are very bad conductors, and it is difficult to make sure that the feeble

Digitized by Google

conductivity they show (when commercially pure) is not due to the presence of traces of salt.

VIII.—*Conductivity of very dilute Acids and Bases.*

The author has been led to the following conclusions :—

"*Acids and bases which dissolve in water without combining with it furnish insulating solutions ; on the other hand, when these substances combine with water in a manner more or less complete they conduct in the same way as salts.*

"But a given acid or a given base often forms with water several different combinations. These combinations are usually unstable in presence of excess of water ; they are dissociated more or less by elevation of temperature and by dilution. It is only in a manner altogether exceptional that a monobasic acid can exist in dilute solutions in the monohydrated state, and without mixture with superior hydrates. Its mode of electrolysis and its conductivity will vary in a corresponding manner. It is therefore not legitimate to liken acids and bases in aqueous solution to neutral salts. The law of equivalents cannot be directly applied to them."

Then follows a twelve page discussion of results to establish these laws. From this I make a few extracts only.

The case of sulphuric acid is interesting, since it can crystallise with either one, two, or four molecules of water, and it undergoes maximum contraction when combined with six atoms. It is known also to possess a maximum conductivity for sp. gr. 1·25. M. Bouty finds that the ratio λ attains a minimum for a concentration about 1/500, as the following table shows :—

Initial concentration	$\frac{1}{30}$	$\frac{1}{60}$	$\frac{1}{120}$	$\frac{1}{240}$	$\frac{1}{480}$	$\frac{1}{960}$	$\frac{1}{1920}$	$\frac{1}{3840}$	$\frac{1}{7680}$
λ	1·917	1·894	1·867	1·856	1·849	1·854	1·881	1·942	2·002

"One does not see how to explain a variation of this kind except by a change in the nature of the electrolyte (*i.e.*, of the dissolved hydrate)."

By making the hypothesis, which Bourgoin made, that the hydrate really decomposed by the current was $S_2O_6\ 6H_2O$, M. Bouty considers that the anomaly of electrolysis as expressed by Hittorf's values of *n*, and also that of conductivity, is explained. These are Hittorf's values of *n* for dilute sulphuric acid. Hydrochloric acid is in much the same condition as sulphuric acid.

*S = ·5574	1·4383	5·415	23·358	97·16	161·4
n = ·400	·288	·174	·177	·212	·206

It conducts as if its molecule contained three equivalents of basic hydrogen. One does not know such a hydrate, but there is probably a mixture of hydrates present.

Oxalic and picric acids are the best conducting organic acids. Other acids conduct hardly at all when strong, and dilution has an enormous effect upon them—probably because they combine with water forming compounds analogous to salts.

IX. *Influence of Temperature.*—To study this, the U tubes of Fig. 1 are turned upside down and immersed in a bath. The result is that for normal neutral salts the conductivity is a linear function of temperature.

$$k = k_0(1 + bt),$$

where b is the same constant for all the salts, and equal to about ·0337. This agrees with Kohlrausch also.

It is noteworthy that Poiseuille gives the quantity of water which flows through a capillary tube, under a given pressure, as proportional to—

$$1 + \cdot03365t + \cdot00021t^2.$$

It is impossible not to be struck with the identity of the principal coefficient in this formula, with *b* in the conductivity formula ; showing that resistance is of the nature of a friction, as Wiedemann surmised.

For abnormal salts the coefficient *b* is a little greater, and a parabolic formula is required at higher temperatures. So, although these salts conduct worse than normal ones to begin with, they improve faster when heated, and accordingly their abnormality decreases with rise of temperature.

For acids and bases the temperature coefficient is rather less, being only ·0119 for sulphuric acid, and ·024 for hydrochloric. Probably warming breaks up some good-conducting hydrate, and so spoils conductivity almost as fast as it otherwise improves it.

"To sum up : I believe I have established that the electrolysis of neutral salts is a simple phenomenon, and that there is only one elementary law of conductivity in harmony with the law of electro-chemical equivalents. Apparent exceptions only reveal to us the complexity of certain solutions which are not directly comparable with those of KCl or K_2SO_4."

* S means the weight of water combined with one gramme of acid.

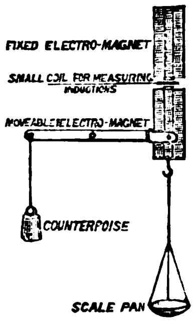
ELECTROMAGNETS.—VI. THE TENSION OF LINES OF FORCE.*

BY R. H. M. BOSANQUET.

The experimental determination of the magnetic attraction corresponding to measured values of magnetic induction has long been in my mind. It has some bearing on my theory of permeability (see *Phil. Mag.* ser. 5, XIX. 1885, p. 87 (note) and p. 94, in both of which places $\mathfrak{B}_2$ is inadvertently printed for $\mathfrak{B}^2$), but its independent interest is considerable.

After the following experiments were arranged, a paper on a somewhat similar subject was read to the Royal Society by Mr. Shelford Bidwell. From the accounts which have been so far published, the method of this paper appears to be entirely different from mine, as the magnetising force and the weight were alone directly measured ; and in other respects the method differs essentially from that which I have adopted.

The sketch represents the instrument constructed for these experiments. This consists of two cylindrical iron magnets, each 20 centim. long and ·526 centim. in diameter. Each is



wound with 1096 coils of wire. One magnet is fixed in a wooden frame, while the other moves exactly under it smoothly and without friction, between two brass collars (not shown), through a vertical distance of about a quarter of an inch. The magnets were at first ground together so as to ensure a perfect contact. The lower or sliding magnet has attached to its lower end an iron hook, which passes through the table and sustains the wooden pan for the reception of the weights. To this magnet also is firmly attached a brass collar, in which are two holes for the pivots of the beam. The beam which carries the counterpoise is about 18in. long; it moves on knife-edges, and has at one end a half-round fork, which embraces freely the collar on the lower magnet, and is pivoted thereto. On the other end of the beam is hung a lead counterpoise exactly balancing the wooden pan and magnet.

The magnetising current was sent through both electromagnets, while the induction was measured† by small coils placed round the point of contact of the two magnets. The inductions were measured by reversal. Weights were carefully added until the contact was broken, and the greatest weight sustained was taken as the observed number. This could be observed with certainty to the nearest ounce.

The first result is that the formula,

$$(W_1) \text{ weight in grammes} = \frac{S\,\mathfrak{B}^2}{8\pi\,.\,981} \text{ (S = section of contact),}$$

derived from (Vol. II.) Clerk Maxwell's "Electricity and Magnetism," p. 256, represents the values well on the whole ; but for very small inductions the weight sustained is several times as great as it should be according to this theory. And this did

* From the *Phil. Mag.* for December.

† For the method see *Phil. Mag.*, ser. 5, XIX., p. 75.

Digitized by Google

not arise from residual induction; for when the magnetising current was interrupted, no power was left to sustain any weight at all.

I therefore framed the empirical formula W, involving both $\mathfrak{B}$ and $\mathfrak{B}^2$; this represents the lower and middle values fairly, but not the highest.

It cannot however, escape notice that the observed values are best satisfied by adding about 4oz. to all weights calculated from W_1. Since, however, this addition must vanish for $\mathfrak{B} = 0$, we cannot thus obtain a general formula. Note that the induction has been forced up to the high value of 18,500. I have shown in recent papers that this quantity has no fixed limit in bar-electromagnets. This accords to some extent with the conclusions of Mr. Shelford Bidwell in the paper before referred to.

Comparison of Observed Weights Sustained with Calculated Weights W_1 and W_2.

$$W_1 = \frac{S\mathfrak{B}^2}{8\pi . 981}, \quad \log S = \cdot 14671.$$

$$W_2 = S(\kappa \mathfrak{B}^2 + l\mathfrak{B}) \; ; \; \log \kappa = \bar{5}\cdot 55391 \; ; \; \log l = \bar{2}\cdot 76660.$$

Finally there are set out a few experiments made with the electromagnets not in contact, but separated to the distances mentioned by slips of card and wood. These experiments are not approximately satisfied by the foregoing formulæ; but they would agree to some extent with W_1 if, instead of the coefficient

$$\frac{1}{8\pi . 981} = \cdot 00004056,$$

we took about half that quantity, say ·000026. The experiments at distance ·2 would require a formula of the type of W_2. At present I am unable to give any explanation of these numbers.

The general truth of the law

$$\text{Tension} \propto S\mathfrak{B}^2$$

is sufficiently established.

In my theory of permeability I have assumed the tension within the magnetic body $\propto \mathfrak{B}$. It is clear that this assumption leads in that case to consequences which correspond with reality, and that the assumption tension $\propto S\mathfrak{B}^2$ does not do so in that case. I am at present unable to explain the divergence between the two points of view.

The weights have all been reduced to lbs. and ozs. to facilitate comparison with the actual experiments.

Batteries were used for weights up to about 5lb.; the dynamo from about 2lb. upwards.

Cuba Submarine Telegraph Company.—The number of messages passing over the lines of this company during the month of November was 3,076, estimated to produce £2,550, against 2,707 messages, producing £2,313 in the corresponding month of last year. The traffic receipts for the month of August, estimated at £2,200, realised £2,163.

ELECTRIC BELLS.

The great interest that was taken in our articles on Electric Bells, and which has been shown more recently in the lectures at the City and Guilds Institute, leads us to think that the following particulars of improvements will be welcomed. The improved designs—actual specimens of which we have before us—are by Mr. Walker Moseley, and refer perhaps more to the indicators connected with the bells than to the bells themselves. The type described and illustrated is that known as the mechanical replacement system. This name is given to a class of indicators which are actuated by electricity only to *expose* the signal or announcement, and not to replace it in its normal position, the replacement being by means of mechanical cams, levers, &c., of various types of construction.

The advantages claimed for this class of indicator are (1) That a larger semaphore may be exhibited with a weaker current than would be required for operating the movement in both directions. (2) Less electrical knowledge is required in fitting. The illustrations show, A the solenoid, B one half of the iron core on which the solenoid is fixed, C the other half of the core, hollow to contain the coiled spring D, and movable so that the projection E opposes the latch L and prevents the disc K from falling.

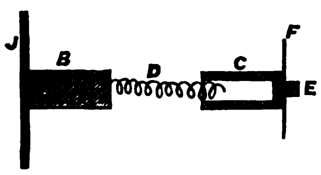

FIG. 1.

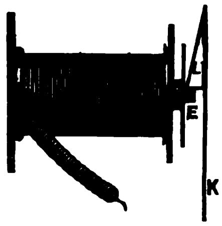

FIG. 2.

The circuit is completed through B, C, G, F, H, J, and it will be observed that the electric current has to produce a force sufficient only to resist the coiled spring D, which is of silver wire, No. 45 B.W.G. Although the spring is so slight it appears impossible for any harm to happen to it becasue it is so completely enclosed.

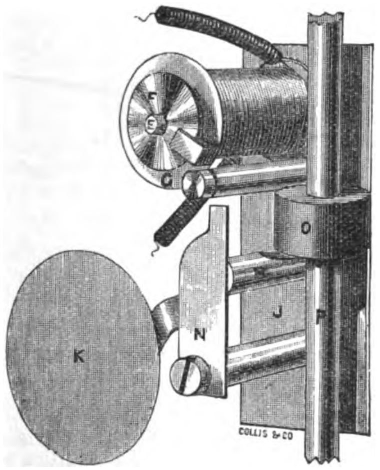

FIG. 3.

The mechanism for replacing the semaphore to its normal position is simple. The vertical bar P carries as many flexible rubber cylinders O as there are indicators in a vertical line. A portion of pivoted cylinder M is cut away, as shown in Fig. 3. The bar P being pulled downwards causes M to rotate the cylinder M about a quarter circle, which causes the latch L to pass over the projection E (Fig. 2), which springs forward again, and holds up the semaphore until another current is passed through the solenoid.

SOUTH KENSINGTON EXAMINATIONS.

HONOURS EXAMINATION.

(Concluded from page 498, Vol. XVII.)

44. Describe and explain fully the experiments and calculations needed for determining the electro-chemical equivalent of an electrolyte.

A.—The electro-chemical equivalent of an electrolyte is defined to be the mass of the electrolyte decomposed in a unit of time by a current of unit strength; or, taking a gramme and a second as the units of mass and of time respectively, and the ampere as the unit of current, the electro-chemical equivalent is equal to the number of grammes decomposed in a second by a current of one ampere.

The quantities to be determined are therefore

The strength of the current	$=C$
The time during which the current flows	$=t$
The weight of the electrolyte decomposed	$=M$

and the electro-chemical equivalent E will be

$$E = \frac{M}{C\,t}$$

These determinations may be made directly in the case of the electrolyte considered, but the products of the decomposition cannot be measured with equal accuracy in all cases, and besides this, the accurate experimental determination is a long process, involving a very large number of measurements of great delicacy, and therefore it is better to determine the electro-chemical equivalent of some suitable substance such as silver, and then to deduce from this the electro-chemical equivalents of other substances.

This we can do when we know the chemical equivalent of the substance, from the law discovered by Faraday—that the electro-chemical equivalents of different substances are proportional to their chemical equivalents (the chemical equivalent of a substance being the quotient of its atomic weight by its valency).

The methods of making the voltameter measurements in the case of silver are described in the abstract of Messrs. Kohlrausch's paper on page 253 of the present volume, and therefore they need not be repeated here. The measurement of the duration of the current presents no difficulty. There remains then the measurement of the strength of the current. This may be done directly by means of an electro-dynamometer, or a tangent galvanometer may be used, and it is then necessary, in addition to knowing the galvanometer constants, to determine the value of the horizontal component of the earth's magnetism at the position occupied by the galvanometer, and at the time of each observation. The authors of the paper above mentioned used three different methods for determining the value of the horizontal magnetic intensity.

(1) *Gauss's Method.*—(1) The time is observed of the vibration of a magnet suspended by a single fibre and performing horizontal oscillations under the influence of the earth's magnetism. This gives the value of the product M H when the moment of inertia of the magnet and the coefficient of torsion of the fibre are known, M being the magnetic moment of the magnet, and H the horizontal intensity of the earth's magnetism. (2) The direction of the magnetic north having been determined, a small magnet is suspended by a fine silk fibre, and the magnet of moment M is placed with its centre at a distance r from that of the suspended magnet, in the same horizontal plane, and due magnetic east for one observation, and due magnetic west for another, and with its axis magnetic east and west. Observations may be made in each position with the north pole of M to the east and to the west respectively, giving four observations for one value of r.

If θ be the deflection observed, the value of the ratio M/H may be found from the approximate formula

$$\frac{M}{H} = \frac{r^3}{2} \tan \theta.$$

Several series of observations may be made in this way with different values of r.

Another series of observations may also be made by placing the magnet M with its centre due magnetic north and south respectively of the centre of the suspended magnet, and with its axis magnetic east and west, when the approximate formula will be

$$\frac{M}{H} = r^3 \tan \theta.$$

The value of H will therefore be obtained by eliminating M by means of the two final equations, which give the values of MH and M/H.

(2) *The Bifilar Magnetometer Method.*—In this method, referred to on page 254 of the present volume, the earth's action on the magnet is determined by suspending it bifilarly, and measuring the torsion required to keep it at right angles to the magnetic meridian, and the deflection it produces in another magnet is observed at the same time. This method does not require a determination of the moment of inertia of the magnet, and no measurements of time are required.

(3) *The Bifilar Galvanometer Method.*—This is similar to the last method, with the exception that the magnet attached to the bifilar suspension is replaced by a coil of wire carrying a current, and therefore the magnetic moment of the magnet is replaced by the product of the strength of the current traversing the coil into the total area included by all its turns—that is to say, the sum of the areas included by each separate turn.

Digitized by Google

When the value of H has been obtained by one of these methods its small variations with the time must be determined, and also the small differences for the different positions occupied by the instruments, as described in the abstract already referred to, which also describes the various precautions and corrections which are required to insure the greatest possible accuracy.

Lord Rayleigh, in his determination of the electro-chemical equivalent of silver (*Philosophical Transactions*, 1884, Part 2), measured the intensity of the current by means of an electrodynamometer with two parallel and equal fixed coils. The readings were always taken of the deflection of the bifilarly suspended small coil on reversing the direction of the current in the fixed coils, which eliminated the effects of terrestrial or other permanent magnetism, and also the action of other parts of the circuit on the suspended coil. It also insured that the heating effect of the current on the fine copper suspending wires of the moveable coil, and any consequent alterations in their mechanical properties (which might alter the restoring force of the bifilar system), should be the same in both sets of readings, and would therefore be eliminated from the result.

45. Explain the sense in which the term "Absolute" is used in connection with measurements of electrical magnitudes. Describe and explain an experimental method of determining, in absolute measure, the resistance of a conductor.

A.—Absolute Measurements.—Measurements of electrical or other magnitudes are called absolute when they are expressed in terms of units which depend only on the three fundamental units, viz., those of time, length, and mass. Results expressed in absolute measure are therefore independent of any quantities depending on the instruments employed, or on the time and place of observation.

Absolute Measurement of Resistance.—The determination in absolute measure of the resistance of a conductor, giving, as it does, an absolute standard of resistance, is one of the most important of electrical measurements, and has therefore been carried out by various physicists. The first determination was made by Weber (see *Phil. Mag.*, 1861), who used two distinct methods.

Weber's First Method.—By suddenly turning a coil of wire about an axis so as to alter its position with regard to the lines of terrestrial magnetic force, a momentary E.M.F. was generated in the coil. A fixed coil in connection with the movable coil had a magnet suspended at its centre, the deflection of which, due to the momentary current, was observed.

The total E.M.F. depends on the dimensions of the movable coil and the terrestrial magnetic intensity, and can be determined in terms of them. The total current is measured by the impulse given to the magnet, the mechanical value of which is measured by the angle of deflection. The resistance of the circuit, consisting of the two coils, is then found by dividing the E.M.F. by the current.

Weber's Second Method.—A powerful magnet was made to oscillate within a coil of wire. The motion of the magnet produces currents in the coil whose reaction on the magnet retards its motion. The resistance can then be determined by comparing the rates of diminution of the amplitude of the oscillations with the circuit closed and with the circuit open respectively.

Sir William Thomson's Method.—This method was used in the determination described in the report of the British Association Committee on Electrical Standards, in 1862. (The reports of the committee are collected in one volume published in 1873).

A coil of wire is made to revolve with constant velocity about a vertical diameter. The motion of the coil across the terrestrial lines of force produces induced currents in the coil whose direction in the coil is reversed at every half turn, viz., when the plane of the coil passes through the E and W direction. Considering the direction of the current with regard to a fixed line in this direction, we see that the direction of the current with regard to either aspect of this line remains unchanged, or, in other words, the direction of the current in space is constant. A magnet suspended at the centre of the coil will therfore be deflected in the direction of its revolution. The force producing this deflection is continually varying, but it is periodic, and its periodic time is small, and therefore the deflection may be made sensibly steady by giving sufficient mass to the suspending apparatus. The E.M.F. of the moving coil, and the current in it, may both be determined in terms of the horizontal magnetic intensity when we know the dimensions of the coil, its angular velocity, and the deflection of the magnet. The resistance of the coil is the ratio of these two quantities, and the measurement of the resistance is independent of the magnetic intensity, which disappears from the ratio. This method was used, with some improvements in details, by Lord Rayleigh in his determination of the Ohm in absolute measure. (*Proc.* Roy. Soc., May, 1881.)

Prof. G. Carey Foster has modified Sir William Thomson's method by using an independent galvanometer to measure the current instead of using the coil itself as a galvanometer, and the conductor, whose resistance is given by the experiments, is entirely distinct from the revolving coil. The chief advantage of this modification is that the conductor whose resistance is to be measured being at rest, may be a coil of wire of any material, and may be immersed in a bath of known temperature. It also enables us to experiment upon independent coils of different resistances. The method is described in detail in the British Association Report for 1881, and in the *The Electrician*, Vol. VII., page 266.

DYNAMO-ELECTRIC MACHINERY.

By J. Hopkinson, M.A., D.Sc., F.R.S., and E. Hopkinson, M.A., D.Sc.

(Continued from page 65.)

A very important problem is to deduce the characteristic curve of a series wound machine from the normal characteristic; in this case $c = C$, and we have

$$1 + \frac{-1}{\nu} 4 \lambda m C \frac{A_2}{2 l_2} = F \left\{ \left(4 \pi n - \frac{4 \lambda m}{\nu} \right) C \right\}$$

taking P R as ordinate of any point in the normal characteristic, cut off Q R equal to $\frac{\nu - 1}{\nu} 4 \lambda m C \frac{A_2}{2 l_2}$, that is, draw O Q so that

$$\tan Q O x = \frac{\nu - 1}{\nu} 4 \lambda m C \frac{A_2}{2 l_2} \Big/ 4 \pi \left(n - \frac{m \lambda}{\nu \pi} \right) C$$

$$= \frac{\nu - 1}{\nu \nu} \frac{A_2}{2 l_2} \frac{\lambda m}{\pi n - \frac{\lambda m}{\nu}}$$

then P Q will represent the induction corresponding to magnetising force $4 \pi \left(n - \frac{m \lambda}{\nu \pi} \right) C$. It is noteworthy that as the current C, and therefore O R increases, P Q, the induction, will attain a maximum and afterwards diminish, vanish, and become negative. That in series wound machines the E.M.F. has a maximum value has been many times observed. The cause lies in the existence of a waste field not passing through the armature, and in the saturation of the magnet core.

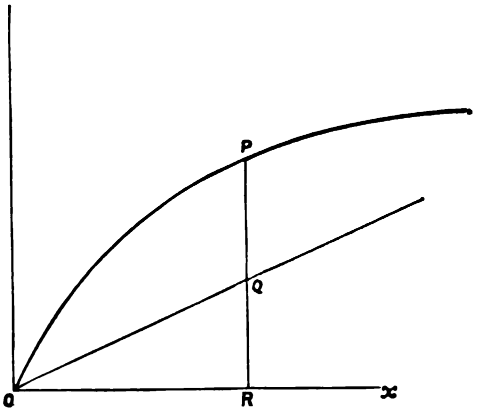

Fig. 6.

The effect of the current in the armature on the potential between the brushes of any machine is the same as that of an addition to the resistance of the armature proportional to the lead of the brushes, and to the ratio of the waste field to the total field, combined with that of taking the main current $\frac{m \lambda}{\nu \pi}$ times round the magnets in direction opposite to the current c.

The preceding investigation tells the whole story of a dynamo machine, excepting only the relation of λ to C in order that the brushes may be so placed as to avoid sparking. The only constant or function which has to be determined experimentally for any particular machine is ν, the ratio of total to effective field, all the rest follows from the configuration of the iron and the known properties of the material.

The following illustrations of the effect of the current in the armature and the lead of the brushes are interesting. In both cases the magnet coils are supposed to be entirely disconnected so that c is zero. First, let λ be negative, short circuit the brushes and drive the machine at a certain speed, a large current will be produced, the current in the armature itself forming the magnet.* Second, let λ be positive, cause a current to pass through the armature, the armature will turn in the positive direction and

* Added August 17th.—This experiment was tried upon a dynamo machine of construction generally similar to that shown in Figs. C, D, E, but with an armature of half the length intended in normal work to give 400 amperes 50 volts at 1,000 revolutions. The magnet coils were disconnected, and the terminals of the armature were connected through a Siemens electro-dynamometer, and the machine was run at 1,380 revolutions. When the brushes were placed in the normal position

Digitized by Google

will act as a motor capable of doing work. In either case, particularly the former, such use of the machine would not be practical owing to violent sparking on the commutator. The following is a further illustration of the formula given above. If we could put up with the sparking which would ensue, it would be possible to make λ negative in a generator of electricity, and thereby obtain by the reactions of the armature itself all the results usually obtained by compound winding.

Efficiency Experiments.

Having discussed the relations subsisting between the configuration of the magnetic circuit of a dynamo machine and the induction obtained for given magnetising forces, and having compared the results obtained by direct calculation with the results of actual observation on a particular machine, the construction of which we have described at length, it appeared of importance to determine the efficiency of the machine under consideration as a converter of energy, when used either as a generator of electricity or as a motor. An accurate determination of the mechanical power transmitted to a dynamo by a driving belt, or of the power given by a motor presents formidable experimental difficulties. Moreover, if the mechanical power absorbed in driving the dynamo be measured directly, any error in measurement will involve an error of the same magnitude in the determination of the efficiency. To avoid this difficulty, we employed the following device.

Let two dynamos, approximately equal in dimensions and power, have their shafts coupled by a suitable coupling, which may serve also as a driving pulley; and let the electrical connections between the dynamos be made so that the one drives the other as a motor. If the combination be driven by a belt passing over the coupling pulley, the power transmitted by the belt is the waste in the two dynamos and the connections between them. By suitably varying the magnetic field of one of the dynamos, the power passing between the two machines can be adjusted as desired. If, then, the electrical power given out by the generator is measured, and also the power transmitted by the belt, the efficiency of the combination can be at once determined. By this arrangement the measurement, which presents experimental difficulties, viz., the power transmitted by the belt, is of a small quantity. Consequently, even a considerable error in the determination has but a small effect on the ultimate result. On the other hand, the measurement of the large quantity involved, viz., the electrical power passing between the two machines, can without difficulty be made with great accuracy.

The second machine was similar in all respects to that already described, and each is intended for a normal output of 110 volts, 320 amperes, at a speed of 780 revolutions per minute.

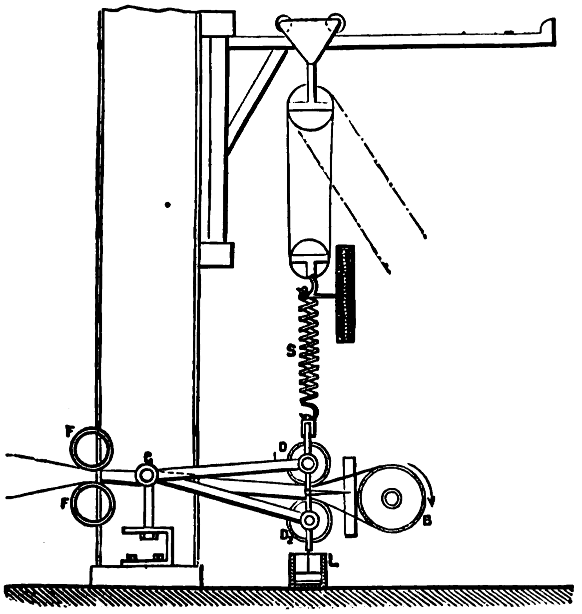

FIG. F.

The power transmitted by the belt was measured by a dynamometer of the Hefner-Alteneck type, the general arrangement being as shown in Fig. F. A is the driving pulley of the engine, B the driven coupling of the dynamo; D, D are the guide pulleys of the dynamometer carried on a double frame turning about the fulcrum C, and supported by a spiral spring, the suspension of which can be varied by a pair of differential pulley blocks attached to a fixed support overhead. When a reading is made the suspension of the spring is adjusted until the index of the dynamometer comes to a fiducial mark on a fixed scale; the extension of the spring is then read by a second index attached to its upper extremity. F, F are two fixed guide pulleys of the same diameter as the pulleys D, D, and having the same distance between their centres, in order that the two portions of the belt may be parallel, and the sag as far as possible taken up. The normal from C to the centre line of either portion of the belt between the pulley A and the guide pulleys = 31·9 cms. The normal from C to the centre line of either of the parallel portions of the belt = 2·4 cms.; and from C to the centre line of the spring = 92·7 cms.

($\lambda = 0$) the current due to the residual magnetism was 52 amperes. By giving the brushes a small positive lead the current was reduced to nearly zero. By giving the brushes a small negative lead a current of over 234 amperes, the maximum measured by the dynamometer, was obtained, and by varying the lead it was easy to maintain a steady current of any desired amount.

Take moments about C; then

$$\text{Tension of the belt} = \frac{92{\cdot}7}{34{\cdot}3} \times \text{tension of the spring.}$$

$$= 2{\cdot}7 \times \text{tension of the spring.}$$

Also the diameter of the pulley B = 33·6cms. and the thickness of the belt = 1·6cm.

Hence the velocity of the centre of the belt in centimetres per second = 1·845 × revolutions of dynamo per minute, and, therefore,

Power transmitted by the belt in ergs per second

$= 2{\cdot}7 \times 1{\cdot}845 \times 981 \times$ tension of spring × revolutions per minute,

assuming the value of g to be 981.

We may more conveniently express the same power in watts ($= 10^7$ ergs per second), and write

Power in watts = ·0004887 × tension of spring × revolutions per minute.

The potential between the terminals of the generator was measured by one of Sir William Thomson's graded galvanometers, previously standardised by a Clark's cell, which had been compared with other Clark cells, of which the electromotive force was known by comparison with Lord Rayleigh's standard. The current between the two machines was measured by passing it through a known resistance, the difference of potential between the ends of the resistance being determined by direct comparison with the Clark standard cell, according to Poggendorff's method. As experiments were made with currents of large magnitude, it was important that the temperature coefficient of the resistance should be as low as possible. To this end we found a resistance frame constructed of platinoid wire of great value. The temperature coefficient of this alloy is only 0·021 per cent. per degree centigrade. (*Proc.* Roy. Soc., Vol. XXXVIII., p. 265, 1885.)

The resistances of the armatures and magnets of the two machines are as follow:—

		Ohms.
Generator	armature	0·009947
	magnets	16·93
Motor	armature	00·9947
	magnets	16·44

The resistance of the leads connecting the two machines was 0·00205 ohm, and of the standard resistance 0·00586 ohm.

In all determinations of resistance, the value of the B.A. ohm was taken as $0{\cdot}9867 \times 10^9$ C.-G.-S. units, according to Lord Rayleigh's determination.

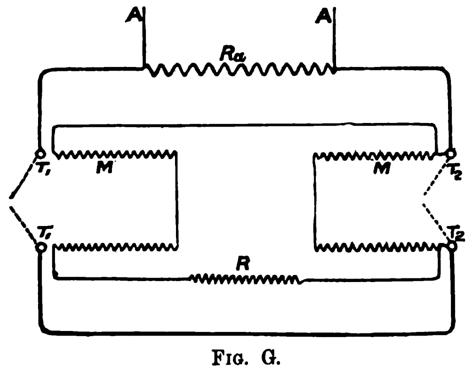

FIG. G.

R_a resistance for measuring current; R resistance for adjusting field of motor; M M magnet coils; A A connections to Poggendorff's bridge; T_1 T_1 terminals of motor; T_2 T_2 terminals of generator.

Fig. G shows the electrical connections between the two machines with the rheostat r inserted in the magnets of the motor dynamo.

In order to ascertain the friction of bending the belt round the pulley B, and of the journals of the dynamo, a preliminary experiment was made with the dynamometer. The combination was run at a speed of 814 revolutions per minute with the dynamos on open circuit and the tension of the spring observed—9,979 grammes. The engine was then reversed, and the dynamos run at the same speed and the tension of the spring again observed—3,629 grammes. The difference of the two readings gives twice the power absorbed in friction, viz., 1,262 watts for the two machines, or 631 watts per machine. This is excluded entirely from the subsequent determinations of efficiency, as being a quantity dependent on such arbitrary conditions as the lubrication of the journals, the weight of the belt, and the angle it makes with the horizontal.

In Table I. column I. is the speed of the dynamos; column II. is the reading of the spring in grammes; column III. is the power transmitted by the belt in watts; column IV. is the potential at the terminals of the generator; column V. is the current passing in the external circuit between the two machines; column VI. is the resistance introduced into the magnets of the motor by the rheostat; column VII. is the power absorbed in the armature of the generator; column VIII. is the power absorbed in the armature of the motor; column IX. is the power absorbed in the magnets of the generator; column X. is the power absorbed in the magnets

of the motor; column XI. is the power absorbed in the connecting leads between the two dynamos, in the rheostat resistance r, and in the standard resistance used for measuring the current; column XII. is the total electrical power developed in the generator; column XIII. is half the power absorbed by the combination less the known losses in the armatures, magnets, and external connections of the two machines; column XIV. is the total mechanical power given to the generator, being the sum of the powers given in columns XII. and XIII.

In Table II. the percentage losses in the armature and magnets of the generator are given, as also the sum of all other losses as obtained from column XIII. in the foregoing table; also the percentage efficiency of the generator, of the motor, and of the double conversion. Column I. is the percentage loss in the generator armature; column II. is the percentage loss in the generator magnets; column III. is the percentage sum of all other losses in the generator; column IV. is the percentage efficiency of the generator; column V. is the percentage efficiency of the motor; column VI. is the percentage efficiency of the double conversion.

In this series of experiments in all cases, from Nos. 1 to 10 inclusive, the brushes, both of the generator and motor, were set at the non-sparking point; but in No. 11 no lead was given to the brushes of the generator, and, consequently, there was violent sparking throughout the duration of the experiment.

In No. 12 the magnets were separately excited with a current giving 113·5 volts across their terminals. The power absorbed must be due entirely to local currents in the core of the armature, and the energy for the reversal of magnetisation of the core twice in every revolution of the armature.

No. 13 gives the results of the experiments on the friction of the bearings and in bending the belt already referred to.

It will be observed that the figures in column XIII. are calculated by deducting the power absorbed in the armatures and magnets, and extraneous resistances from the total power given to the combination as measured by the dynamometer. They must therefore include all the energy dissipated in the core of the armature, whether in local currents or in the reversal of its magnetisation; also the energy dissipated in local currents in the pole-pieces, if such exist; also the energy spent in reversing the direction of the current in each convolution of the armature as they are successively short circuited by the brushes. Further, it will include the waste in all the connections of the machine from the commutator to its terminals and the friction of the brushes against the commutator. A separate experiment was made to determine the amount of this last constituent, but it was found to be too small to be capable of direct measurement by the dynamometer. Moreover, from the manner in which the figures in this column are deduced, any error in the dynamometric measurement will appear wholly in them. Since, undoubtedly, the first two components enumerated are the most important, and the conditions determining their amount are practically the same throughout the series, the close agreement of the figures in the column are a fair criterion of the accuracy of the observations. Probably 100 watts is the limit of error in any of the measurements. Such an error would affect the determination of the efficiency when the machines were working up to their full power to less than ½ per cent.

It has been assumed that the sum of these losses is equally divided between the two machines. This will not accurately represent the facts, as the intensities of the fields and the currents passing through the armatures differ to some extent in the two machines. The inequality, however, cannot amount to a great quantity, and if it diminishes the efficiency of the generator it will increase the efficiency of the motor by a like amount, and contrariwise. In No. 11 of the series the effect of the sparking at the brushes of the generator is very marked, the power wasted amounting to at least 250 watts.

If it be assumed that the dissipation of energy is the same whether the magnetisation of the core is reversed by diminishing and increasing the intensity of magnetisation without altering its direction, or whether it is reversed by turning round its direction without reducing its amount to zero, a direct approximation may be made to the value of this component. (J. Hopkinson, *Phil. Trans.*, Vol. 176 (1885), p. 455).

The core has about 16,400 cubic centims. of soft iron plates, hence loss in magnetising and demagnetising when the speed is 800 revolutions per minute $= 16{,}400 + \frac{800}{60} + 13{,}356$ ergs per second $= 292$ watts.

Referring to Table II. it appears that the efficiency approaches a maximum when the current, passing externally between the two machines, is about 400 amperes. Let C be the current in the armature, ρ its resistance, W the power absorbed in all parts of the machine other than the armature, then if the speed is constant, the efficiency is approximately $\frac{E C - W - C^2 \rho}{E C}$, where E is the electromotive force. This is a maximum when $\frac{W}{C} + C\rho$ is a minimum, which occurs when $W = C^2 \rho$; when the loss in the armature is equal to the sum of all other losses. For the machines under consideration the experimental results verify this deduction. But in actual practice the rate of generation of heat in the armature conductors, when a current of 400 amperes was passed for a long period, would be so great as to trench upon the margin of safety desirable in such machines. Of the total space, however, available for the disposition of the conductors, only about one-fourth part is actually occupied by the copper, the remainder being taken up with insulation, and the interstices left by the round wire. If the space occupied by the copper could be increased to three-fourths of the total space available, while the cooling surface remained the same, the current could be increased 75 per cent. and the efficiency increased 1·3 per cent. approximately, as all losses other than that in the armature wires would not be materially altered.

The loss in the magnets is also susceptible of reduction. It has already been shown that for a given configuration of the magnetic circuit and a given electromotive force the section of the wire of the magnet coils is determinate. The length is, however, arbitrary, since within limits the number of ampere convolutions is independent of the length. An increase in the length will cause a proportionate diminution in the power absorbed in the magnet coils. If the surface of the magnets is sufficient to dissipate all the heat generated, then the length of wire is properly determined by Sir William Thomson's rule that the cost of the energy absorbed must be equal to the continuing cost of the conductor.

(To be continued.)

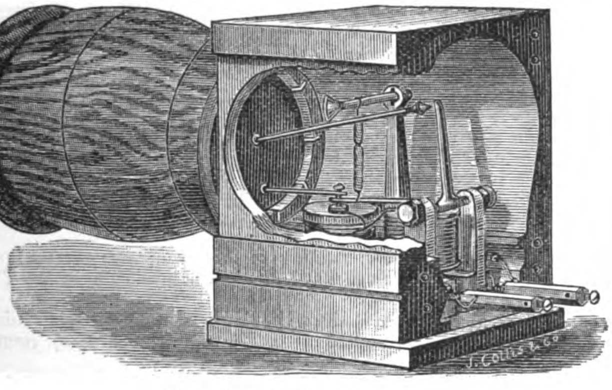
THE "HOUSE" TELEPHONE OF 1868.

In the accompanying illustration, which we reproduce from the *Scientific American*, is shown an instrument which, although not designed for the purpose, yet actually constitutes an efficient telephone transmitter and receiver, and was patented by Mr. Royal E. House in the year 1868. For the following particulars respecting this instrument and its inventor we are substantially indebted to some articles which have recently appeared in the columns of our contemporary above referred to. Mr. House, who was born in the year 1806, and who is still living, was engaged in the early development of the electric telegraph in America, and was working on parallel lines with Prof. Morse. In 1868 he patented the instrument here figured, under the title of "Improvements in Electro-Phonetic Telegraphs," the idea being to obtain a highly-sensitive apparatus capable of working as a sounder with very small currents, and so doing away with the necessity of using relays and repeaters upon Morse circuits. Although the instrument does not appear to have come into actual operation, there can be no doubt that it was perfectly capable of fulfilling the purpose required. If, indeed, Mr. House had fully perceived the extreme delicacy of his apparatus, the discovery of Prof. Bell would have been anticipated by eight years.

With regard to the instrument itself, its construction is so clearly shown in the figure that a verbal description would be superfluous. The object of the rod which is attached to the

Digitized by Google

lower part of the diaphragm, and which the inventor termed a "limiter," was to prevent the armature from receding too far from the poles, for which purpose its extremity is provided with an adjustable stop. Probably, however, this particular detail has no special value. The motion of the armature contemplated by the inventor was only one-hundredth of an inch. Unfortunately, the model which was deposited in the United States Patent Office was accidentally destroyed by fire, but a pair of instruments constructed in accordance with the specification and patent drawings when used as transmitter and receiver are said to give results "immeasurably superior to anything shown in the Bell patents of 1876 or 1877." We are further told that "sibilants are as clearly transmitted as any other sounds, and its work was fully as good as that of the Bell telephone and Blake transmitter of to-day."



The House Telephone.

The instrument will shortly be introduced as a commercial article by the Wallace Telephone Company, of New York.

PHYSICAL SOCIETY.—Nov. 27.

Prof. W. G. ADAMS in the Chair.

The following papers were read:—*On a Method of Measuring the Coefficient of Mutual Induction of Two Coils*, by Prof. G. CAREY FOSTER, F.R.S. The two coils are for convenience designated by P and S (primary and secondary). The method, as originally devised, consists of two parts. (1) Observing the swing of the needle of a galvanometer needle placed in series with the secondary coil when a current of strength γ is started in the primary. (2) Placing the galvanometer and a condenser of known capacity c as a shunt between two points, A and B, of the primary circuit, such that the first swing of the galvanometer needle, on completing the primary, is the same as in (1). It is easily seen that under these conditions $M=crr_1$, where M is the coefficient to be determined, r=resistance between the points A and B, and r_1 = resistance of galvanometer and secondary coil. The method requires the value of γ to be the same in the two experiments, and facilities for varying r without altering γ. To overcome these difficulties, the arrangement has been modified so as to make it a null method. The connections remain the same as in (2), excepting that the ends of the secondary coil are connected to the terminals of the galvanometer through a variable resistance with no self-induction. If p be the resistance of the secondary coil, and variable resistance when adjusted, so that on completing the primary circuit the integral current through the galvanometer is zero, it is shown that $M=cpr$, where c and r have the same meaning as before. For let A and E be the potentials of the galvanometer terminals at any time t, y the resistance of galvanometer, q the current through it, and N and L the coefficients of self-induction of the galvanometer and secondary coil respectively. Then considering the path from A to E through the secondary coil we have $$A-E=px+L\frac{dx}{dt}-M\frac{dy}{dt};$$
for path through galvanometer
$$A-E=qy+N\frac{dy}{dt}.$$
Equating these and integrating from $t=0$ to $t=\infty$ we get
$$p\int_0^{\infty} x\,dt - My=0.$$
Since $\int_0^{\infty} x\,dt$=charge of condensor, $=C\,y\,r$, we see that $M=cpr$.

It is easily shown that if $L=M$, then $A-E=0$ for all values of t. Hence the galvanometer might in this case be replaced by a telephone.

By inversion, the method could be used for determining the capacity of condensers in absolute measure, if M be known. The author thinks the method will be useful for dynamo machines, and gave a series of numbers obtained by experiments on different coils, showing that it gives consistent results. Mr. C. V. Boys suggested that by arranging a switch to change the connections from (1) to (2) in rapid succession a steady deflection might be obtained, and thought that this would enable very small coefficients to be determined. Remarks by Prof. Forbes, Prof. Adams, and Prof. Perry were answered by Prof. Foster and Dr. Fison.

On the Critical Mean Curvature of Liquid Surfaces of Revolution, by Prof. A. W. RÜCKER, M.A., F.R.S. The paper is chiefly mathematical, and deals with liquid surfaces of revolution attached to two circular rings, the planes of which are at right angles to the line joining their centres. By "mean curvature" the author designates: *Half the sum of the reciprocals of the two principal radii of curvature of the surfaces.*

Maxwell has shown in his article on "Capillary Action" ("Enc. Britt.") that if the film be a cylinder, a slight bulge will cause an increase or decrease in the mean curvature according as the length is $<$ or $>\frac{\pi}{2}$ times the diameter. If $l=\frac{\pi}{2}d$, then a small change in the volume of the surface will modify its form, but will not alter the mean curvature. Thus the mean curvature of such a cylinder is evidently a maximum or minimum with respect to that of other surfaces of constant mean curvature, which pass through the same two rings at the same distance apart, and which differ but little from the cylindrical form. Hence the cylinder may be said to have a *critical mean curvature* when the distance between the rings is $\frac{\pi}{2}$ times their diameter. If the distance between the rings is altered a similar property is possessed by some other surface. The author's paper investigates the general relation between the magnitude and distance apart of the rings and the form of the surfaces of critical curvature.

If x is the axis of revolution, then the equation to a liquid surface of revolution is given by the expressions
$$x=\alpha E+\beta F, \quad y^2=\alpha^2\cos^2\phi+\beta^2\sin^2\phi,$$
where F and E are elliptic integrals of the first and second kinds respectively, of which the amplitude is ϕ and the the modulus $K=\sqrt{\alpha^2\beta^2}/\alpha$.

As usual $\triangle=\sqrt{1-k^2\sin^2\phi}$, whence $y=\alpha\triangle$; and if $K=\sin\theta$, then $\beta=\alpha\cos\theta$, and since $\alpha>\beta$, α and β are the maximum and minimum ordinates.

The results show that as θ increases from 0° to 90° the surface of critical mean curvature is an unduloid with limits of cylinder and sphere, when $\theta=0$ and $\theta=90°$ respectively. When θ passes from 90° to 180° the surface is a nodoid, with limits of sphere, and a circle whose plane is perpendicular to the surface of revolution. In the third quadrant the surface is still a nodoid, the limits of which are a circle and the catenoid. Finally, in the fourth quadrant the surface is an unduloid, the limits being the catenoid and cylinder. Experiments were shown proving that with cylindrical films, where $l<\frac{\pi}{2}d$, increase of internal pressure produced a bulging, whereas if $l>\frac{\pi}{2}d$, a bulging was produced by decrease of pressure. From this it is evident that if the interiors of two cylindrical films whose $l<\frac{\pi}{2}d$ be connected, stable equilibrium will result; whereas if $l>\frac{\pi}{2}d$ there will be unstable equilibrium. These facts were illustrated experimetally with great success. After some remarks by Mr. C. V. Boys the proceedings terminated.

PROPOSED BILLS, &c., IN THE NEXT SESSION.

The West Metropolitan Tramways Company notify their intention of applying to the Board of Trade for a Provisional Order, to be confirmed by Parliament next Session, to empower the company and others using their tramways to work them by means of carriages and engines propelled by electricity or other power, in addition to or in substitution for animal power. Authority will be asked for to empower the Board of Trade to make, and the company to enforce by-laws, &c., for regulating the use of electricity or other power.

The Northampton Street Tramways Company will make a similar application.

Notification is given of an intended application to the Board of Trade by a company to be incorporated as the Littlehampton Electric Tramway Company, or by Magnus Volk and others, for a Provisional Order to enable them to make a tramway at Littlehampton from the railway station there along the roads to the esplanade at Littlehampton, and to work the tramway by electric motive power, "or by such other power as the Board of Trade may approve."

In the Bill for which the Weston-super-Mare Improvement Commissioners intend to apply to Parliament power will be asked for to provide and maintain for their town hall, offices, and other establishments, telegraphic and telephonic communication with any parts of the district.

The Cockermouth Local Board will apply to Parliament for leave to bring in a Bill to enable them to produce and supply electricity for all purposes within certain limits to be defined, and for that purpose on any land for the time being belonging to them to make and maintain works for the production, storage, supply, and distribution of electricity for the purposes of light, heat, and motive power, and to exercise with respect thereto all or any powers of the Electric Lighting Act, 1882, the Gasworks Clauses Act, 1847, and the Gasworks Clauses Act, 1871, and other rights and powers

Digitized by Google

which may be necessary or expedient for the purposes in question. By other clauses the Board will ask for powers to purchase the undertaking of the Cockermouth Gaslight and Coke Company, by agreement or compulsorily, and also to enable them to acquire, hold, and use patent rights and licences for and in relation to the production, storage, and supply of electricity, the manufacture, supply, and use of gas, and the manufacture and conversion of residual materials and products.

LEGAL INTELLIGENCE.

The Anglo-American Brush Electric Light Corporation (Limited) v. R. E. Crompton and Co.

This was an appeal heard by Lords Justices Cotton and Bowen on behalf of the defendants from an order of Vice-Chancellor Bacon, which was made in chambers on the 2nd Nov. this year, directing them to deliver further particulars of objections in addition to those particulars of objections already given by them to the plaintiffs pending an action for infringement of patent.

Mr. Butcher appeared for the appellants ; Mr. G. C. Graham representing the Company.

The former opened his case by saying that the action was one for an infringement of the patent granted to the plaintiffs' predecessors in the year 1878 for the construction of dynamo electric machines. The patent was amended by disclaimer in 1885, and the action was commenced. The defendants put in their defence. They denied the validity of the patent, and they had also delivered the particulars of the objections on which they intended to rely at the trial, those objections having been delivered on the 11th August last. The objections, he might say, were a plea of invalidity, want of utility, and insufficiency of specifications, and last an objection, which was the most material in the case, as to what was called disconformity, which was stated in the usual way, as far as he had been able to discover, and which said "that the alleged invention, described in the complete specification as amended, was a different invention from that described in the provisional specification " It was with regard to this latter objection that the present appeal was lodged. His contention was that the question of conformity or non-conformity was one to be decided on the construction of the two specifications, and to ask the defendants for any further particulars of objection than had been already furnished, and which, he believed, fulfilled all the statutory requirements, was in reality to ask them to disclose the nature of their defence at the forthcoming trial. The order really amounted to this:—"What are the heads of the arguments by which you intend to ask the Court, as a matter of law, to say that the final specification varies from the provisional?" It appeared to him that the plaintiffs could not possibly be taken by surprise. They knew the precise objection that was raised against them, and if they were prepared with evidence to construe their patent they would be ready to meet any objection.

Their Lordships having heard the arguments of Mr. Butcher, both concurred, without calling upon the other side, in declining to interfere with the order of the lower Court.

Gilman v. The Gulcher Electric Light and Power Company.

This was an appeal by the plaintiff from that portion of the judgment of Mr. Justice Grantham, who tried the case without a jury, which disallowed his claim for fees as a director of the defendant company in respect of the period from the 31st December, 1884, to the 14th of May, 1885, when he resigned his position as a director.

The case was heard last Friday by the Master of the Rolls and Lords Justices Lindley and Lopes. Mr. Candy, Q C., appeared for the plaintiff, the defendant company being represented by Mr. L. E. Pyke

Mr. Candy opened his case by saying that by the Articles of Association of the Company the remuneration of the Directors was fixed at the lump sum of £1.500 per annum, which should be divided between the members of the Board in proportion to their attendances, or as they may determine. By certain calls on the plaintiff's shares, which were not disputed, the amount sought to be recovered was reduced to £64. 7s. 6d. Mr. Gilman was very willing to go to meetings after December, 1884, but the other Directors were so hostile to him that they threatened to break his head, and to break up every meeting at which he attended, and consequently he resigned. At the trial he was prepared, if necessary, to adduce evidence in support of that statement, but his learned friend, Mr. Pyke, said it was quite immaterial, because he rested his contention, which was successful with Mr. Justice Grantham, upon the wording of Article 52 of the Company's Articles of Association, which he read. At the time Mr. Gilman joined the Board, the principle of division of the £1,500 was to give to the Chairman £500, and to each of the remaining four Directors £250. He then proceeded to read several minutes of the Board passed at various times, waiving part of the Directors' fees, and apportioning the remainder among the members of the Board, the effect of which was to deprive the plaintiff of the amount claimed.

The Master of the Rolls, without calling upon the other side, in delivering judgment, said that he agreed with the ruling of the learned judge who tried the case. The plaintiff became a Director of the Company under certain Articles. According to these Articles he had a right to a certain remuneration. The true construction of Article 52, dealing with the remuneration of the Directors, was that they were to receive £1,500 per annum. That was what the Company undertook to pay. So far as the present dispute was concerned the Company were not bound to pay at all. "The remuneration shall be £1,500 per annum, and shall be divided between the members proportionately to their attendances, or as they may determine." There was no limitation as to time. If there was no resolution of the Board to alter that Article the remuneration was to be in proportion to their attendances. Now, what would happen in the case of a Director who had shown no attendances? Nothing could be paid in that case, and yet the £1,500 would have to be divided. Having regard to the construction of the Article how that £1,500 was to be distributed, it was absolutely within the discretion of the Directors, and they had, by resolution, come to a determination upon it. It was said it was *ultra vires* to come to the determination because it was after Mr. Gilman had ceased to be a Director. But he could see nothing which said that the Board which came to the determination was not the Board. On the contrary, it was the Board. It was said that they behaved with gross injustice to the plaintiff. His answer to that was that he could not help it. There was nothing laid before him that led him to suppose that it was unjust. Very likely there were good reasons for it. He did know. If they said, "Your conduct has been such that we cannot associate with you," he saw nothing unjust in that. But probably because of that there might be the ground of an action against the Directors, but not against the Company. But if a Director stayed away for a whole year and the other Directors appropriated the money that he otherwise would have had, he saw nothing unjust in that, because the extra work, in consequence of that non-attendance, was thrown entirely upon the other Directors. He therefore upheld the judgment of the learned judge.

Lord Justices Lindley and Lopes also concurred.

COMPANIES' MEETINGS.

River Plate Telephone and Electric Light Company (Limited).

An extraordinory general meeting of this Company was held at the offices, 34, Walbrook, on the 1st inst., under the presidency of Mr. Thomas Lloyd.

The Secretary (Mr. R. Rodgers) having read the notice convening the meeting, the minutes of the last meeting were taken as read, confirmed, and signed by the Chairman.

The Chairman then said that as the amalgamation or sale to be submitted for the shareholders' approval depended on the terms of the agreement which had been come to, the most satisfactory course would be for the solicitor of the Company to state all the essential points of the agreement, so that the shareholders might understand what was submitted to them.

Colonel Gouraud thought that as much as possible of the agreement should be read, of course leaving out the "whereases."

The Solicitor (Mr. Godlee) said he would leave out nothing that was of importance. The agreement was made between this Company, the United Telephone Company of the River Plate, and Mr. Rodgers on behalf of the new company to be formed, and to be called the United River Plate Telephone Company (Limited). The Consolidated Telephone Company and Mr. Frank Williams Jones were also parties to the agreement for the purposes of the last clauses. The agreement recited that it was proposed to effect an amalgamation of the businesses of the River Plate Company and the United Company for the transfer thereof to the new company. With that view it was intended that each of the two companies should pass special resolutions for voluntarily winding up and appointing liquidators. It also recited that the new company was about to be incorporated, and that a Memorandum and Articles of Association had been prepared. Those Articles had been signed subject to such modifications as might be agreed upon by all the three companies who were the principal parties to the agreement, and it was recited that the Consolidated Company were largely interested in the River Plate Company, and that Mr. Jones was a director of, and largely interested in, the United Company. The operative part of the agreement was as follows:—"This agreement is conditional on two things—the passing of the special resolutions aforesaid within six weeks from the date hereof (that is the 22nd November) and the adoption of this agreement by the liquidators of the two companies and by the new company in such a manner that it should become binding on them respectively before the 1st of January next, subject, as aforesaid, that each of the two companies should sell and transfer the good will of its business in the Argentine Republic and Paraguay, and the assets mentioned, to the new company, who should purchase and take over the same." Having read the assets of the River Plate Company, and of the United Company, which were to be transferred, he said that the consideration for the sale and transfer was as follows:—To the River Plate Company and to the United Company £145,000 each ; the new company will also pay in cash to the United Company the cost price of the whole of the new telephones, &c., which had not been used.

The Chairman said that this particular clause was put in because the United Company carried on a sale business, which the River Plate Company did not. But the new company was not to be bound to take over more than £10,000 worth of such stock, and Mr. Jones, who was Chairman of the United Company, though he did not bind himself to the figures, expressed the belief that the amount of stock would be between £8,000 and £10,000.

The Solicitor (continuing) said that the new company was also to pay the United Company in cash a sum not exceeding £3,000 on account of certain items which he read. Of the consideration to be paid to each company £20,000 was to be satisfied by the issue to each company of 200 debentures of the new company for twenty years at 7 per cent., and the new company had the right at any time after the 1st January, 1892, to pay off those debentures at the expiration of six calender months' notice by paying a bonus of £10 per cent. each. Each company

Digitized by Google

also agreed to accept £40,000 in fully paid up ordinary shares in the new company at par, and such further portion of the balance of £125,000 as the new company might desire to pay in shares instead of cash. The new company, within twenty days after its incorporation, was to offer to the public for subscription at least 34,000 of its £5 shares, and to use its best endeavours to place them. The special clause to which Mr. Jones and the Consolidated Telephone Company were made parties was the last clause, by which they agreed that they would not directly or indirectly compete with the new company in the Argentine Republic or Paraguay, or assist any other person or company to carry on any opposition to, or compete with, the new company in those Republics for ten years from the date of the agreement, the new company, in consideration of this agreement, agreeing that in case Mr. Jones died or ceased to be a member of the Board of the new company before its annual meeting in 1891, the new company would pay to him, his executors, &c., a sum at the rate of £166 per annum from the date of his ceasing to be a Director up to such annual meeting, together with the same proportion of all sums above £1,500 which should be payable to the Directors of the new company from his ceasing to be a Director to the said annual meeting, as he would have received if he had still remained a Director of the new company. The schedule consisted simply of the form of debentures.

The CHAIRMAN presumed that they would not require that to be read.

Mr. C. L. W. FITZGERALD said that he understood the £20,000 of debentures referred to would simply go to the old debenture holders.

The CHAIRMAN said that that was so.

Mr. FITZGERALD said that the old debenture holders were giving up 2 per cent. of their interest under the agreement.

Colonel GOURAUD stated that he was asked to attend the meeting on behalf of several shareholders in the Company, who took their interest in it when he was Chairman of the Company, which he ceased to be two years ago. It was thought by those gentlemen that the information given in the circular was meagre. He could quite appreciate that it would have been difficult to go into very many details without giving the text of the agreement to the shareholders, which perhaps for some reasons would not have been expedient. He certainly would like to have an opportunity of reading the agreement, but not in such a way as one would go through it at a meeting and then hand it back.

The CHAIRMAN said he would remind Colonel Gouraud that a confirmatory meeting had to be held a fortnight hence, and that the present meeting committed itself to nothing except the principle. In the interval the shareholders would have had further time to consider the subject.

Col. GOURAUD said he was aware that there would be a confirmatory meeting, but he thought that all information possible should be given at the first meeting. With that object he would therefore ask one or two questions. He had been unable to take any of the assets which the River Plate Company would turn over to the new company and compare it with the language used by the Solicitor in reading the next clause referring to the assets to be turned over by the United Company. As to the Articles of Association of the new company, that was a very important matter, and he thought the shareholders should have the opportunity of judging for themselves what those Articles were by being able to read them. By these remarks he was far from wishing to imply that he had any want of confidence in the work of the Directors, or what they recommended the shareholders to ratify. He had from his own experience in the Company a very keen appreciation of the difficulties which the Directors must have had in bringing the negotiations with the competing (the United) company to a head. With all his experience he had never met with any gentleman so difficult to negotiate with as Mr. Jones, who was so keen to his own interests. As he understood it, the Directors had accomplished what the old Board strove constantly for two years to do. Mr. Jones seemed now to be getting a good many extras, but perhaps he was entitled to them; and the provision as to salary in the event of his ceasing to be a Director was unusual. But probably there was reason for that. As to the shares in the new company, he presumed that the amount of the shares as indicated as the amount to be offered to the public was settled with reference to the questions of a Stock Exchange quotation, and so on. He also suggested that provision might be made enabling shareholders in the present companies to have a preference in the taking up of the shares of the new company, providing that that could be done without their risking the obtaining a quotation on the Stock Exchange. Great progress had been made in the past in the face of extraordinary competition, and he believed himself that they would have a marvellous future. The Consolidated Company and Mr. Jones had agreed as to not competing with the new company for ten years; but he did not see why the arrangement should not be indefinite for not competing. He thought it would be advantageous if the meeting could be adjourned for a day or for a couple of hours.

The CHAIRMAN said that, as regarded an adjournment beyond the 1st of December, Christmas was very close upon them, and it was thought desirable that the new company should not be postponed to months hence in the new year. They had to hold a confirmatory meeting, and he thought it was obvious that they could not adjourn the meeting beyond that day. They had called the meeting at the earliest opportunity and they found themselves tied by time. With regard to the point about the stores, the shareholders were probably aware that the River Plate Company only did an exchange business, whereas Mr. Jones's company did a sale business as well. He had sold to the new company his exchange business and also his sale business, and it was thought only reasonable, as he had a stock of material on hand for selling purposes, that that stock should be taken over at cost price.

Colonel GOURAUD asked what cost price meant.

Mr. JONES replied that the cost price was the invoice prices that the Company paid for the material. They paid, for instance, £3 for a complete telephone.

The CHAIRMAN said that one of the objects in view was a quotation of the shares.

Mr. QUILTER, M.P., understood that the stock that was to be taken over was efficient material.

The CHAIRMAN said that that was the case.

Mr. FITZGERALD pointed out that the agreement stated that th stock was to be new and unused.

Colonel GOURAUD said he believed that it was the intention of Mr. Jones that the material should be such as could be used in the prosecution of the business.

Mr. JONES assented, and added that in the event of any question arising as to any material there would be no objection raised to the point being referred to an arbitrator.

The CHAIRMAN said that the reason for the proposed payment to Mr. Jones, in the event of his ceasing to be a Director, was that Mr. Jones conceived that in being asked to guarantee that he would not compete with the new company he was asked to do something out of the ordinary, and as the Directors had some experience of Mr. Jones's enterprise and ability in competing with them, and they were very anxious that in the future if that gentleman ceased to be a Director they should not have to face the same formidable competition, they made the arrangement with him referred to in the agreement.

Colonel GOURAUD expressed himself satisfied with the explanation.

The CHAIRMAN said he thought he had already answered the point of what was to be transferred from the two companies to the new company. Practically, the two companies turned over their whole exchange business, and Mr. Jones's company, in addition, turned over the sale business. The latter received precisely the same price as the River Plate Company, except that the new company would take over at cost price the material in hand which Mr. Jones had for sale. The provisional agreement made early in the year in Buenos Ayres stipulated that the amalgamation in Buenos Ayres should take place on the 1st of March last. When they met finally to conclude the agreement the question arose whether they should go back to the 1st of March or fix a present or future term for the amalgamation, and, on the whole, they had thought it better to fix on the date mentioned in the agreement. The shareholders would remember that if they went back to the 1st of March they would have to hand over the whole of the receipts since the 1st March to the new company, and the new company would not have any benefit from the great reduction in the expenses which they hoped would result from the amalgamation. As the business, however, of both companies had been extended since then, and as the new company would benefit by the extension, it had been judged only fair that the expenditure in extending the business should be paid for. That was to say, if they had done more in extending the business than Mr. Jones's company they would get paid for what they had done in excess of that gentleman's company, and *vice versâ*.

Colonel GOURAUD said that was a very reasonable arrangement.

A SHAREHOLDER wished to know whether either company had obtained all the concessions in the important towns in the Argentine Republic.

Mr. JONES replied in the negative, and added, as a matter of fact, that there would come into the possession of the new company a sales contract in connection with a new company which was to be started at Rosario.

The SOLICITOR said that there was a difference in the assets of the two companies to be handed over. The two clauses in the agreement referring to that matter were identical, except that the United Company handed over its business in Uruguay to the new company, while the River Plate Company did not do so. The United Company would also hand over its sale contracts with their benefits and obligations.

The CHAIRMAN, in answer to Mr. Quilter, said that Mr. Jones guaranteed that he would not compete with the new company, and the new company except his sale contracts, took over nothing in Uruguay. The River Plate Company retained its business in Uruguay, and the new company bought nothing there but Mr. Jones's sale contracts. He was sure that the Consolidated Telephone Company would strongly object to guaranteeing that it would not sell or do business in Uruguay.

Mr. QUILTER said that his object was not to prohibit the Consolidated Company, but as he understood they were taking over Mr. Jones's sale business in the Argentine Republic, and that part of the world, he presumed that it was intended that Uruguay, as far as Mr. Jones was concerned, should be included in it.

The CHAIRMAN said that as a matter of fact it was not so included, Mr. Jones having said that he would guarantee only as far as the Consolidated Telephone Company guaranteed. Mr. Jones, however, handed over his sale contracts for ten years, and the price he got was the first five years' profits. If there was no profit he got nothing, and therefore if he competed with the company he would practically put the price out of his own private pocket.

Mr. QUILTER said that his suggestion was in view of future harmony being secured.

Mr. JONES said he thought there were far more reasons for the new company to anticipate opposition from the Consolidated Telephone Company than from himself.

Mr. FITZGERALD thought that that remark was not just. The Consolidated Company was giving up a good business which they were doing on the River Plate; but they would most distinctly object to agree not to supply instruments to Monte Video. If Mr. Jones wanted the Consolidated Company to do that all that he (the speaker) could say was that he must stand up for the shareholders of that company. If Mr. Jones liked to add the word "Uruguay" as regarded his (Mr. Jones's) company, he thought he could do so.

Mr. JONES considered it quite a bagatelle, and would consent if he were requested.

Mr. FITZGERALD said there was one matter which the Chairman had not put exactly before the meeting. The capital of the River Plate Com-

Digitized by Google

pany he believed was about £92,000. They were selling that business in Buenos Ayres, which had cost a considerable sum of money, for £125,000. Whether in shares or cash would depend very much indeed on the way the public took the shares. But he thought he might say the result would be that the shareholders in this old company would also have a very considerable sum of money returned to them in cash, and also a certain sum which would be the amount according to the rules of the Stock Exchange that they could have in shares. If any gentleman in the room wished to apply for shares in the new company he was perfectly entitled to do so as well as the public, but the absolute result would be, as far as he could make out, that they would get in shares about half a share each for each share they held, and in cash about £4. 11s., and also the back dividends. That was the result that he worked out, and it would come to something like £8 a share.

The CHAIRMAN said that he had not all the data before him for giving an estimate, and the meeting must take Mr. Fitzgerald's estimate on the responsibility of that gentleman alone.

Mr. QUILTER, in answer to Colonel Gouraud, intimated that if any privilege were given to the shareholders in connection with applying for shares of the new company, which the general public did not enjoy, the risk would be run of a Stock Exchange quotation not being granted.

Colonel GOURAUD presumed that the Articles of Association and agreement would be open to the shareholders between the present and the next meeting.

The CHAIRMAN: Certainly.

Colonel GOURAUD said he took it that the liquidation was somewhat unusual, as the River Plate Company were selling only a portion of their business, while they were retaining a very important business in Monte Video, which would be confided to the management of the liquidators. He did not know how far a meeting such as this could control liquidators in that way, but he would like to have some expression of opinion as to what their intentions were in regard to the business that was to be retained.

Mr. QUILTER said he thought it would be better to deal with that matter when the question of liquidators arose.

The CHAIRMAN then said that the first resolution he had to propose had reference to the appointment of liquidators, and was as follows:—"That it is expedient to effect an amalgamation of this Company, except as regards its Uruguay business, with the United Telephone Company of the River Plate (Limited), and that with a view thereto this Company be wound up voluntarily, under the provisions of the Companies Acts, 1862 to 1883, and that Thomas Lloyd, of 34, Walbrook, E.C., Esquire, and C. L. W. Fitzgerald, of 4, Hercules-passage, E.C., Esquire, be and they are hereby appointed liquidators for the purposes of such winding up, at a remuneration to be fixed by the Company."

The CHAIRMAN continuing, said that since the notice was sent out Mr. Grewing wished to withdraw, and Mr. Fitzgerald agreed to take his place.

At the suggestion of Mr. QUILTER it was decided to divide the resolution into two parts, the first part ending at the figures "1883."

On the motion of the CHAIRMAN, seconded by Major FITZGERALD, this resolution was agreed to; as was also subsequently the latter part as to the appointment of liquidators, on the motion of the CHAIRMAN, seconded by Mr. R. E. BATEMAN.

Mr. QUILTER asked what control the shareholders had over the liquidators.

The SOLICITOR said that the liquidators had the same power as the Directors, and they could summon a general meeting. He believed they were in the same position as Directors, and they were bound to hold a meeting once a year.

The CHAIRMAN then proposed the next resolution, as follows:—"That there be conferred upon the liquidators all the powers which can be conferred upon liquidators under the provisions of the Companies Act."

Major FITZGERALD seconded the motion.

Mr. QUILTER asked whether any extraordinary powers were proposed to be given to the liquidators.

The CHAIRMAN: Our legal adviser says no.

Colonel GOURAUD inquired whether any powers could be reserved.

The SOLICITOR: They are the ordinary powers of liquidators.

Colonel GOURAUD said the liquidators might have to carry on for years the business that was retained.

The SOLICITOR replied that the liquidators were bound to summon a general meeting every year.

Mr. QUILTER said that the liquidators could not be removed except by an order of the Court.

The SOLICITOR replied that that was so.

The resolution was altered by the addition of the following words:—"With the assistance of a consultative committee consisting of the following gentlemen, with power to add one to their number"—the gentlemen selected being Mr. Quilter and Mr. Arthur Baker, of the Stock Exchange.

On the motion of Mr. R. E. BATEMAN, seconded by Colonel GOURAUD, a resolution was passed to the effect that the remuneration of the two liquidators should be £500 between them.

The CHAIRMAN then proposed the following resolution:—"That the agreement expressed to be made between the Company, of the first part, the United Telephone Company of the River Plate, of the second part, Richard Rodgers on behalf of the United River Plate Telephone Company, Limited, which is about to be incorporated, of the third part, the Consolidated Telephone Construction and Maintenance Company, Limited, of the fourth part, and Frank Williams Jones, of the fifth part, be and the same is hereby approved, and that the liquidators be and they are hereby directed to adopt the said agreement on behalf of this Company, and to carry the same into effect."

Major FITZGERALD seconded the motion.

At the instance of Mr. Fitzgerald the following words were added to the end of the resolution:—"With power to agree to such modifications in the Articles of Association of the new company as they may think fit."

The resolution as thus altered was unanimously agreed to.

On the motion of Colonel GOURAUD, seconded by Mr. QUILTER, a vote of thanks was passed to the Chairman and Directors.

The CHAIRMAN acknowledged the vote, and said it was only fair to Mr. Jones, that gentleman having been referred to, to say that he (the Chairman) had found him, while extremely clever, at the same time a very fair and courteous negotiator. He had never met an abler negotiator, but he never asked to meet a fairer one.

The proceedings then terminated.

Blackpool Electric Tramway Company.

The second annual meeting of the shareholders in this Company was held on Saturday, Mr. R. Horsfall, mayor of Halifax, presiding. In moving the adoption of the report, which recommended that a dividend of 5 per cent. be paid, and that £800 be set aside as a reserve fund (the report was given verbatim in our last issue), the Chairman said that he met the shareholders with very much more confidence than he did at their last meeting. They had overcome many difficulties in the working of the line during the year, and he thought they had now got everything in a satisfactory condition, and that the Company had been placed upon a sound basis. The Company had not met with that support from the inhabitants of Blackpool, and the Corporation especially, which it was entitled to; and the Directors had been compelled to appeal to the Board of Trade on the question of running the cars on Sundays—a proceeding which the Corporation had very strongly objected to. £100 was voted to the Directors, and a vote of thanks to Messrs. Elwell-Parker and Co. for their numerous and valuable services to the Company was unanimously adopted. The dividend was declared, and the retiring Directors, Messrs. Morris (Halifax), Moseley (Manchester), and Oddie (Halifax), were re-elected.

BUSINESS NOTICE.—Mr. C. E. Zimdars, Telegraph Engineer of London and New York, asks us to state that his business address is No. 327, Gray's Inn-road, W.C., and not Hatton-garden.

NOTES.

The Brussels International Exhibition of Telephony.—The date of the opening of this Exhibition has been fixed for the 9th January.

The West Coast of America Telegraph Company.—The gross earnings of this company for the month ending 30th November amounted to £4,190.

Direct Spanish Telegraph Company.—The estimated traffic receipts of this company for the month of November amounted to £1,860, against £2,030 in the corresponding period of last year.

Lighting of Railway Carriages in Germany.—The Administration of Railways in the State of Wurtemberg have decided to adopt electric lighting for all first and second class carriages upon their lines.

The Institution of Civil Engineers.—At the next ordinary meeting, Tuesday, December 14th, the discussion on the paper by Dr. John Hopkinson, F.R.S., on "The Electric Lighthouses of Macquarie and of Tino," will be continued.

The Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending December 3rd were £3,688, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Rochester, N.Y.—The Telephone Company at Rochester, N.Y., having given notice of an intended revision of tariffs, whereby the rates for business houses would be largely increased in comparison with those for private residences, out of 700 subscribers 600 have given notice to terminate their contracts.

West Hanney Church.—The installation in the nave of this church, to which we made some reference last week, consists of ten 16 candle-power lamps, supplied with current from a primary battery of 8 large sized cells. The battery was supplied by the Electric Apparatus Company, and the expense was undertaken by the Rev. J. MacDougall, the vicar of the parish.

Chatham.—On Monday evening a party of gentlemen paid a visit to Chatham, with a view of inspecting the Thomson-Houston electrical installation erected there by Messrs. Laing, Wharton, and Down. The plant has been erected in Messrs. Scott's timber saw mill, and is sufficient to light 18 arc lamps, which are distributed in the streets and a few shops in the neighbourhood.

Brazilian Submarine Telegraph Company.—The directors of this company, on Wednesday, declared an interim dividend of 3s. per share, or at the rate of 6 per cent. per annum, free of income tax, for the quarter ended September 30, 1886, payable on the 24th inst. The books of the company will be closed from the 17th to the 23rd inst. inclusive. The traffic receipts for the week ended 3rd instant amounted to £4,515.

Paris.—The Exhibition of the Sciences and Industrial Arts at the Palais de l'Industrie was closed upon the 7th inst. A large number of diplomas of honour have been awarded to the various exhibitors of electrical apparatus. The representatives of the Thomson-Houston Company obtained honours for arc lighting, Messrs. Woodhouse and Rawson for their incandescent lamps, and Messrs. Gaulard and Gibbs for their transformers.

Proposed Electric Telegraph Jubilee Exhibition.—We are informed that at the weekly meeting of the Council of the Balloon Society, held in the Library of the Royal Aquarium, Capt. Parry, R.N., in the chair, the following resolution was proposed by Mr. Rogers, C.E., seconded by Mr. Merritt, and carried unanimously:—"That an Electric Telegraph Jubilee Exhibition should be held to celebrate the invention of telegraphy in 1837."

Great Northern Telegraph Company.—We are advised that telegraphic communication with China, Hongkong, and Manila by this company's route is restored, and the line is again working well. The traffic returns for November were £21,200; and the receipts for the period from 1st January to 30th November, £239,000; for the corresponding months of 1885 and 1884, £264,440 and £257,480 respectively.

Lighting of a Corn Mill.—Messrs. Wilson Hartnell have recently placed an installation in a large corn mill at Leeds, a class of work which this firm makes a speciality. The number of lights at present in use is about 220, but provision is made for 450. A Crompton No. 15 compound-wound machine is used, and is driven by counter shafting from the mill engines. The dynamo switch-board is of slate, of Hartnell's patent type.

The International Cable Conference.—The meetings of this body which have stood adjourned since May last were resumed in Paris on the 7th inst., but owing to some of the signatory States not yet having given in their adhesion to Clause 12, the Conference has been again adjourned until July 1. The clause referred to provides for the investigation by a committee of the Conference of all laws which may from time to time be passed in any of the signatory States, and which may have any direct or indirect bearing upon submarine cables.

The Severe Gale.—A gale of exceptional severity passed over the United Kingdom on the 8th inst., and was accompanied in many districts by thunder and lightning. The church of St. Andrew, in Princes-street, Lambeth, was struck by lightning, and a large stone cross was precipitated into the roadway. Telegraph lines were blown down in all parts of the country, and it is long since such a general interruption of telegraphic communication has been experienced. At Brighton the Electric Railway, which suffered so severely in the gale of October 17th, has again received some damage, but not apparently of a serious character.

New York Tramways.—The Julien system of electric tramways, in which secondary batteries are employed, has been introduced into New York. A car is now running upon the Third Avenue line, and the system is attracting much attention. Hitherto very little has been done in America with secondary batteries for this particular purpose—and, indeed, comparatively little for any other purpose. It is stated that the Third Avenue Tramway Company has definitely decided to abandon horse traction in favour of some form either of mechanical or electric propulsion—probably the latter—but the particular system has not yet been finally selected. This company at present employs over 3,000 horses.

Visit to Messrs. R. E. Crompton's Works at Chelmsford.—The Mechanics' Institute of Chelmsford paid a visit last Wednesday to Messrs. R. E. Crompton and Co.'s electric light works. The visitors, who numbered about 400, were shown round the works and had the machinery and the different stages of manufacture explained to them by the pupils and staff. A search light was in operation in the tower on the roof of the works, from which a good view can be obtained of the surrounding country on all sides. A short popular lecture was given later on by Mr. Crompton, and afterwards a more

Digitized by Google

detailed explanation by Mr. Swinburne. Refreshments were liberally supplied in the manager's house close by.

TELEGRAPH SCHOOLS IN AMERICA.—We subjoin the following paragraph from an article relating to American telegraph schools in one of our Transatlantic contemporaries:—"In the school alluded to the method pursued is what is called the 'g. b.' After a poor devil or deviless has pounded away for a specified length of time the 'lord high executioner' decides that he or she is a failure, and—pht-t-t, the individual disappears. If there are friends and backbones to make a fight, why, a compromise is effected, and part of the money is refunded, but generally the bitter pill of disappointment is swallowed, and the pupil looks up a half interest in some other fraud or disappears in the scum of the city's whirlpool."

LECTURE AT THE ARCHITECTURAL ASSOCIATION.—Mr. Maxmilian Clarke has been good enough to send us a copy of his paper on "Artificial Lighting," which was lately read before the "Advanced Class of Construction" of the above association. In referring to this in our last issue we attributed the paper, in mistake, to Mr. John Slater. Mr. Clarke's paper is one which we are sure must have proved of very great interest to his audience, and we are very glad to find that steps are being taken to bring the advantages and the methods of electric lighting prominently before the rising architects of the day. The rooms were lit by incandescent lamps provided with current from E.P.S. cells, which the company had kindly lent for the occasion.

THE BRIGHTON ELECTRIC LIGHT COMPANY.—At the annual meeting of the Brighton Electric Light Company, the chairman reported that the business of the company was increasing very satisfactorily, and that the directors had decided to double their engine and dynamo power, at an expenditure of £200. This extension of the plant would bring the lighting power of the station up to 2,000 incandescent lights. The mains of the company now extended over a distance of 11 miles. The chairman said he considered that the dividend of 4 per cent. on the first year's trading, after providing for depreciation of plant, &c., was an encouraging one, and he hoped to be able at the annual meeting next year to announce a large increase in this dividend. To provide for the extension of the company's plant, a call of £800 had been made upon the present shares of the company, making them fully paid, and a further issue, to the extent of £1,200, being part of the capital of the company, had been decided upon.

PENINSULAR AND ORIENTAL COMPANY.—Speaking, on Tuesday, at the annual meeting of the Peninsular and Oriental Steam Navigation Company, Mr. T. Sutherland, M.P., the chairman, in the course of his remarks, said:—In connection with this question (referring to the new contract for the conveyance of the India and China mails), I may mention a fact of some interest, perhaps more in a scientific than a commercial point of view, though it bears a very important influence in relation to ourselves commercially—namely, that we have been able to employ the electric light in passing our ships through the Suez Canal during a portion of the last six or eight months. That is an alteration in the mode of working our vessels which will greatly tend to reduce the period of transit hitherto necessary for passing through the Suez Canal, and it will enable us to give a special success to the canal as a mail route. It is a curious fact that we find it to be practically easier to pass our ships through the canal at night by means of the electric light than in the day time.

PROPOSAL FOR ELECTRIC LIGHTING OF TRAINS IN TUNNELS.—With regard to our remarks under this heading in last week's "Notes," a correspondent from Edinburgh sends us an account of an arrangement precisely similar to the one which we suggested, and which, by a somewhat singular coincidence received its first experimental trial upon the Glasgow Underground Railway a few days previously. A conductor has been laid down between the rails from Queen-street station to the College station, and a trailing collector is lowered or raised by the guard at will. The experiments proved thoroughly satisfactory, and it is probable the company will adopt it for permanent use. In such a case as this, where the total distance is not great, it is of course practicable to supply current from a single station to all the trains, and at each tunnel upon the system, and this is the method which is proposed to be used at Glasgow. But when it is desired to provide for the illumination of trains while passing through tunnels at considerable distance apart, the use of secondary batteries will evidently be the only practicable plan.

PRIVATE WIRES IN THE UNITED STATES.—A recent article in the *New York Herald* states that there are now no less than 150,000 miles of private wires in or converging upon New York alone, of which about two-thirds of the whole are maintained by the Western Union Company. These figures sound almost fabulous, but many of the lines are of great length; more than twenty go to Chicago (over 1,000 miles), while wires to Boston, Philadelphia, Washington, and other distant cities also account for a considerable portion of the mileage. The annual rate for a special wire between New York to Chicago is from £5,000 to £6,000 per annum. Most of these twenty lines are in the hands of the great grain speculators. In the summer immense numbers of private lines are required between New York and the great watering places, as Newport, Saratoga, and Long Branch. Naturally, however, the local lines between New York, Brooklyn, and the various suburbs are the most numerous. These wires are erected and maintained by the companies, but the operators are provided and paid by the subscribers themselves. Morse recorders are almost universally employed.

THE ELECTRIC LIGHT AT THE BRITISH MUSEUM.—We recently mentioned the fact that the electric light in the British Museum Reading Room had one evening been extinguished an hour or more before the usual time. We are very pleased to learn from *Industries* that this inconvenient circumstance did not arise, strictly speaking, from any breakdown of the machinery, but from the fact that the engineer in charge made the discovery that some evil-disposed person or persons (supposed to be an *employé* under notice of dismissal) had put some sand into one of the engine bearings. It was therefore thought necessary to send notice to the librarian that the light would be discontinued in ten minutes' time. Unfortunately it was not possible to collect the books and dismiss the readers in the time of grace allowed, and consequently there were still a large number of persons in the room when the lights went out. By the aid of a few lanterns, however, in the course of another quarter of an hour the room was cleared. We are assured that efficient steps have been taken to prevent a repetition of such a dastardly act, and the frequenters of the Reading Room can rest content that they will not again be subject to such annoyance.

LA SOCIÉTÉ INTERNATIONALE DES ELECTRICIENS.—It is scarcely possible to congratulate this society upon having attained so high a standard in respect of the papers which are read at its monthly meeting as its position and title might justly lead us to expect. For instance, of the two papers read at the November meeting, while one (to which we make further reference in another note) is decidedly interesting, and

Digitized by Google

may possibly have some future importance, yet it is difficult for an English electrician to speak of the other without something approaching contempt. The title is not unpromising :— "Sur quelques inventions historiques peu connues." Under this head the society listened to a *very* brief description (accompanied by a diagram) of Dr. Hopkinson's "invention" of the characteristic curve which the author was good enough to commend as a really useful idea. The author also exhibited the outline diagram of a decidedly abortive dynamo, which it appears he discovered some years ago in the correspondence columns of *The Electrician.* We have also—and equally *apropos* of nothing—one of Page's motors, *Anno*, 1850, a machine not without interest in itself, and a further diagram of an arrangement for winding field-magnet coils in several sections, and putting one or more in circuit with a radial switch. No single remark of any technical or theoretical interest is discoverable throughout the effusion, and its only merit is its comparative brevity. But surely La Société Internationale des Electriciens, if it is to justify its existence at all, should be able to provide somewhat more substantial fare than this.

Conversazione at King's College.—The King's College Engineering Society held a very successful *conversazione* in the college buildings on Friday, 3rd inst. A very large and interesting collection of scientific apparatus was exhibited in the great hall, and in the various laboratories numerous experiments were performed. A working model of a telpherage line, constructed by Mr. W. P. Adams, a student of the college, attracted much attention. Among other electrical apparatus exhibited in action there was a very fine display of "vacuum" and "radiant matter" tubes; an inductive coil experiment to show the degree of vacuum in a glow lamp; Prof. Forbes' thermopile galvanometer (exhibited by Mr. F. H. Nalder); a collection of microscopes provided with minute glow lamps illuminating the stage (the current for these little lamps was supplied by a set of Clammond thermopiles); and an Immisch dynamo and motor. These last were to have been exhibited in action, the motor driving the dynamo and being itself supplied with current from a Crompton machine in the basement, but owing to the excessive demands made during the evening upon the gas engine which drives the Crompton, it was not deemed advisable to run the motor for any length of time. In the museum of King George III. the remarkable historical collection of scientific apparatus, of which the College is justly proud, was exhibited. Here were to be seen Daniell's original battery, the old five needle dial telegraph; electric machines of the last century, and many of Wheatstone's original experimental apparatus. We have confined our description to the electrical apparatus, though of course there was much else to look at, which, together with an organ recital in the chapel, and a concert in the great hall, ensured a thoroughly enjoyable evening to all present.

Another New Method of Reproducing Designs.—Under the title of "Effluviography" (given to it by the discoverer), we published last week a note upon the above subject. We have now a further account of a process which effects a similar object in a somewhat different manner. This is due to Dr. Boudet, of Paris, and was described at length at the November meeting of the Société Internationale des Electriciens. It will, however, be seen that although the learned doctor does not appear to have made any reference to the fact, his experiments, though decidedly interesting, are nothing more than a further development and amplification of the very ancient experiment known under the name of Franklin's portrait. The paper contains an account of numerous modifications; but the main idea is the same in all, namely, that a high tension discharge (either from a Rhumkorff coil, or preferably from a static machine) is caused to take place across the plates of a condenser between which the design is placed. The dielectric may either be an air space—in which case the design may consist in a cut, engraved, or embossed metallic surface—or it may be a sheet of cardboard, paper, wood, glass, or other insulator—in which case the design may also be cut or stamped, or even drawn in crayon upon its surface. In every case the reproduction appears upon that plate which is attached to the *positive* pole of the machine. By this method Dr. Boudet has succeeded in obtaining a large number of accurate reproductions from a single crayon drawing, all the minutest features of the original being well preserved. If a stencil-plate, say of cardboard, be placed between two sheets of glass backed by metal plates, after the discharge has been taken, no trace is at first apparent upon the glass; but if the surface be now breathed upon the design appears. It may be permanently fixed by exposure to the fumes of hydrofluoric acid. Cameos or intaglios, such as medals, coins, or seals, may best be reproduced by covering the surface with plumbago, or with almost any powder, whether conducting or non-conducting. If any part of the design is to be omitted it is sufficient to moisten it with the least trace of alcohol.

The "Lancet" on the Lighting of Railway Carriages. In an article upon this subject the *Lancet*, after pointing out the short-sighted policy of the railway companies in the matter of providing insufficient light in their carriages, proceeds as follows:—"Meanwhile there is higher ground that must be occupied. A very considerable amount of actual mischief is done by the long persistent refusal of railway companies to provide suitable means of lighting their carriages. This is a subject on which much has been written, but to very little purpose. The only possible explanation of the great neglect which has been shown in this particular respect is that chairmen and directors have not the courage to incur the needful expenditure. There is, of course, no sort of difficulty in the matter. If only the will existed, plenty of ways and means of attaining the object in view could be found. The Metropolitan and District Companies, not because they are more liberal than others, but because the line lying underground the carriages must needs be lighted, have shown how gas may be employed; and other companies have, by experiment at least, demonstrated how electric apparatus may be adapted to locomotive lighting purposes. It has also been made plain that either gas or the electric light can be economised by being placed under the control of one of the companies' officials, to be turned up when passing through tunnels by day or when it grows dark at night, and turned down again at pleasure. In short, there is no sort of excuse for the failure to provide a proper amount of light for both ordinary and extraordinary purposes. Our appeal must be to the public, and we would point out that the practice of reading in railway carriages, as for the most part at present lighted, is one that ought to be discontinued. The instances in which injury is inflicted upon persons with weak or irritable eyes are very numerous; and cases of cerebral irritation set up by habitual efforts to read in dimly-lighted carriages are of frequent occurrence. Until the cry for more light elicits a response, it will be simply prudent to abandon the attempt to beguile the time spent in railway journeys by reading. Better do this than sacrifice sight or induce brain disease."

Telegraph Clerks and the Royal Commission.—A meeting of the Plymouth telegraph staff was held at the Borough Arms on Saturday evening, for the purpose of electing a committee to decide as to the best steps to be taken for collecting evidence and statistics for the executive committee at Liverpool to lay before the Royal Commission at present

Digitized by Google

inquiring into the working body of the Civil Service establishments. Gratitude was expressed for Mr. Fawcett's efforts on behalf of the clerks, but some of the defective points in his scheme were pointed out, one of which is that no less than fifteen years must elapse from the date of appointment as an efficient clerk (say eighteen years of age) before a salary of 38s. per week can be obtained; beyond this sum the salaries of the present junior staff cannot rise, judging from the ordinary rate of promotion. Moreover, the salary held to be comparatively fair at the start, viz., 16s. per week, is at 21 years of age only 20s. 6d. It was stated that in the telegraph department there were men with fifteen years' service who had not yet reached the maximum of their class (38s.), whereas in the Post Office clerks with sixteen years' service were in receipt of higher salaries than those with twenty-eight years' service in the Telegraph Department. It was also pointed out that no appointments as postmasters or to fill vacancies in the surveyor's or engineering departments, had taken place from the Plymouth telegraph office within the past 17 years, consequently the only promotions to the first class were caused through increase of work and a corresponding increase of staff. The following resolutions were passed unanimously:—"That the present system of promotion by selection irrespective of merit is strongly condemned." "That this meeting expresses satisfaction at the appointment of a Royal Commission to inquire into the working of the Civil Service, in the hope that it will ensure an examination into the cause of dissatisfaction existing amongst the telegraph clerks and the partial success of the telegraphs, and its especial thanks to Mr. Puleston, M.P., for obtaining the inclusion of the telegraph department within the scope of the inquiry." It was decided that a copy of this resolution be sent to Mr. Puleston, M.P.—*Western Morning News.*

THE CONDENSER ON TELEPHONE CIRCUITS—AN ERRONEOUS CONCLUSION.—In a note recently presented to the *Academie des Sciences*, M. Charles Cros describes some experiments on the use of a condenser in connection with telephone circuits. Having constructed an artificial line, consisting of coils of insulated wire, connected with a commutator, by which any required number of coils in series could be placed in or out of circuit, with a pair of telephones, the author added coils until the articulation of the receiving telephone could no longer be understood. He then inserted a condenser at the middle of the line, and found that the volume of sound was at once largely augmented. M. Cros proceeds to suggest the practical application of his discovery (?) upon long lines; and then theorises upon the subject with especial reference to the analogy between electric currents and fluid motion. He has further constructed an elaborate arrangement of pipes and closed chambers, whereby he obtains a mechanical analogue of the circuit in question. Without staying to examine this part of the research, it may be safely stated at once that M. Cros has entirely overlooked one most important factor, the neglect of which vitiates both his arguments and his deductions. M. Cros is dealing with alternating currents, yet he has left entirely out of sight the question of the coefficient of self-induction of the circuit. If the experiment is repeated under practical conditions – that is, upon a straight wire of sufficient length to prevent intelligible communication by virtue of its resistance pure and simple—it is tolerably certain that the introduction of a condenser would no longer have the effect described. In default of facilities for such an experiment, ordinary resistance coils, wound non-inductively, might be employed. This question of the employment of alternating currents upon open circuits containing both condensers and self-induction has been very fully investigated from the theoretical side by Mr. T. H. Blakesley, who in his book on "Alternating Currents" (page 47) writes:—"The result may be summed up in the following words: When an alternating generator operates upon a circuit which is closed by a condenser without leakage, and which possesses a coefficient of self-induction, then there is a certain period of alternation which may be given to the generator, at which the condenser might be replaced by a junction introducing no additional resistance into the circuit, *the coefficient of self-induction being also removed*, without disturbing the current." Although the conditions are somewhat modified when we employ a telephone transmitter in which the period of alternation is continually varying, yet it is easy to show that there will be a wide range for the value of the capacity of the condenser in relation to the coefficient of self-induction of the circuit, within which the general effect will be to enable communication to be effected through a larger number of coils such as those used by M. Cros.

THE SOCIETY FOR THE PROTECTION OF LIFE AND PROPERTY FROM LIGHTNING.—We have received from Mr. W. M'Gregor, M.S.T.E. (secretary of the above society *pro tem.*), a small pamphlet setting forth the objects and methods of this society. It is proposed to establish a central bureau, which, among other things, shall undertake the examination of architects' and builders' plans in reference to chimneys, steeples, and towers, the periodical inspection and testing of lightning conductors, the registration of persons properly qualified for the last-named duty, to bring about *esprit de corps* amongst architects, engineers, builders, and manufacturers of lightning conductors, and, lastly, "to advise and encourage Governments, officials, heads of departments, the clergy, churchwardens, local boards, and others whose duty it is to protect life and property to employ the means available." It cannot be denied that, however laudable may be the aims and intentions of this society, they have succeeded in setting them forth in a manner which will, we fear, do much to hinder their own usefulness, and, indeed, can best be characterised as "fussy." Architects and builders will scarcely be so ready to submit their plans for the criticism of a self-constituted body as the society seems to imagine. The society's certificate of qualification as to ability to test a lightning conductor, will not, we fear, be very eagerly competed for, and possibly "Governments, clergy, churchwardens, and others, may not always consent to receive advice and encouragement." It must not, however, be supposed that we entertain any hostility to the society itself, which, indeed, may prove very useful in awakening public attention to the importance of securing an adequate and efficient system of lightning conductors on all buildings of any height or importance. But after all we suspect that so long as the fire insurance companies do not move in the matter it will be a difficult and thankless task to stir other people. But, in addition to this practical business, the society proposes to organise a scientific section who are to undertake the investigation of the meteorological and other phenomena attendant upon lightning. They are more particularly to observe the geological features of districts in which thunderstorms are of frequent occurrence, likewise the physical characteristics of the surrounding country, and, further, in the department of biology observations are to be made upon the bodies of the slain. This is division B. Division C has as its object the discussion and enforcement of "means by which to educate public opinion to the pitch of demanding municipal or other inspection and control of lightning conductors." Lastly, division D undertakes the formation of a museum, library, and laboratory. Every member on payment of his entrance fee and subscription is entitled to have his house examined by the society's inspector.

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 75.)

In order to obtain a high degree of sensibility the wire must be wound very closely round the magnet. In Sir William Thomson's galvanometers there are generally three or four or more magnets made from watch spring and attached to the back of a small mirror of silvered glass, the axes of the magnets being all parallel, and their north poles pointing in the same direction. The mirror with its attached magnets is suspended by means of a single silk fibre within the circular coil, and the interior diameter of the coil just allows sufficient freedom for the mirror to swing.

In the dead beat galvanometer the mirror is placed in a brass tube which it nearly fits, and a brass or copper stop is fixed just behind it, while a plate of glass is fixed just in front, allowing the needle only just sufficient space to swing through the greatest angle required.

The resistance which the needle experiences in churning the air in this confined space, and through the currents which it induces in the metal tube and stop when swinging, produces such an amount of damping that the needle when set swinging comes almost immediately to rest.

In the marine galvanometer the needle is suspended by a fibre which is attached both at the top and bottom of the instrument, and thus exposed to considerable tension. This prevents the mirror from swinging like a pendulum. The variable action of the earth and the ship's magnetism, as the vessel swings, is obviated, according to the principles explained above, by enclosing the instrument in a wrought-iron case, leaving only a window open for the entrance and exit of a beam of light. The controlling magnet is placed within the iron case. The instrument is thus protected from the action of magnetic bodies outside it in the same way as electrical instruments are protected from the action of external electrified bodies when they are surrounded by closed conductors or wire cages.

In the mirror galvanometers, the deflection of the needle is observed by means of a beam of light from a lamp, which is reflected from the mirror, and falls on a graduated scale. The reflected ray turns through double the angle turned through by the mirror. The light from the lamp is usually allowed to pass through a hole in a screen, across which a vertical wire is stretched, and a convex lens is introduced in the path of the beam, which causes an image of the slit and wire to be formed upon the scale. By employing a very light mirror in a dead beat galvanometer telegraphic signalling may be read after passing through a submarine cable.

In the sensitive galvanometers above referred to the current is not strictly proportional to the tangent of the angle through which the mirror is deflected, for, as the needle turns, its poles get farther aware from the wire, and the force exerted upon them by the current is diminished. In order that the current may be strictly proportional to the tangent of the angle of deflection, the magnetic field produced by the current, as well as the permanent field within the instrument due to the earth and the controlling magnet (if there be one), must be constant throughout the space in which the needle moves. To secure this the controlling magnet is dispensed with, and the interior diameter of the coil made very large in comparison with the length of the needle. An instrument so constructed cannot be very sensitive. A galvanometer of this class is usually called a *tangent* galvanometer or *tangent compass.*

Helmholtz improved the tangent galvanometer by employing two equal coils placed parallel to one another, and having a common axis, the distance between the coils being equal to the radius of either. The needle is very short, and is suspended midway between the coils. As the needle swings, and its north pole recedes from one coil so that the force exerted upon it by the coil is diminished, the same pole will approach the other coil, whose action upon it will be correspondingly increased. The same will be true of the south pole, and thus the forces exerted by the current upon the poles of the magnet will not sensibly vary as the latter swings.

Fig. 5 shows the lines of force in Helmholtz's form of the instrument, and it will be noticed that for some distance near the centre the lines are practically parallel. The lines of force in each case are due only to the current in the coils of the instrument.

In the sine galvanometer the coil is capable of being turned about a vertical axis, and when the needle turns in obedience to the current the coil is turned after it by hand, until the coil is in the same plane with the magnetic axis of the needle, and the angle through which the needle and coil are turned is observed. It will be found that as the coil is made to follow the needle the deflection of the latter will increase, but if the current be not too great for the instrument, the coil will at length overtake the needle. The *sine* of the angle of deflection will then be proportional to the current, and since the needle is always in the plane of the coil when the deflection is observed, the length of the needle may be nearly equal to the internal diameter of the coil, for its poles are kept in the same positions relative to the wire.

When a current passes through a coil of wire, magnetic lines of force are found to encircle the wire, and all pass through the coil in the same direction. These lines of force may be regarded

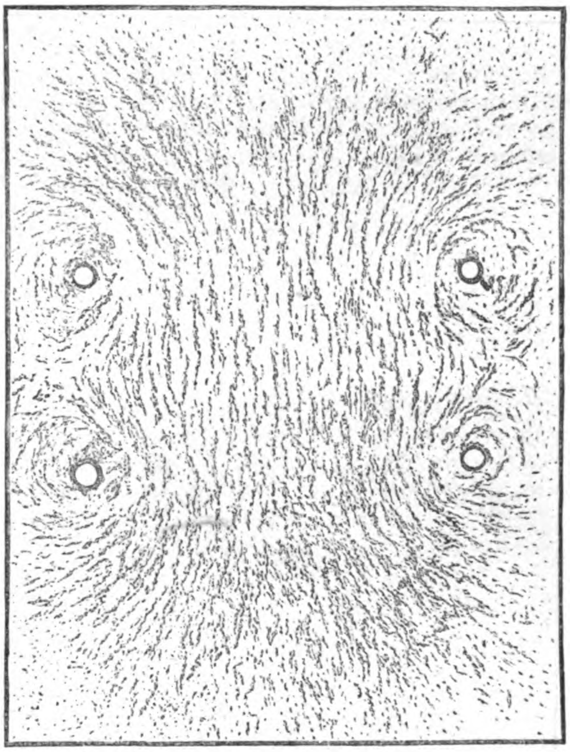

FIG. 5.

as proceeding outwards from one face of the coil, just as they proceed from the north pole of a magnet, and inwards towards the other face, as the lines of force converge towards the south pole of a magnet. Hence, as far as its action upon everything outside the coil is concerned, the coil of wire through which a current is flowing will behave like a plate of steel, having the same periphery as the coil, and magnetised so that one face consists wholly of a north pole, and the other face of a south pole. If a right-handed screw were rotating with the current, and carrying the coil with it in its motion, the face of the coil which is advancing would be the north pole, and that which is receding the south pole.

If two such magnetised discs of steel were free to move they would turn so that the south face of one disc is presented to the north face of the other, and would then attract each other. Fig. 5 shows the lines of force due to a pair of coils, in each of which the current is flowing in the same direction.

Hence, two coils conveying currents will, if free to move, turn so that the currents flow round each coil in the same direction, and will then attract one another, since the magnetic fields they produce, and on which their mutual action depends, are identical with those of the steel discs or "magnetic shells."

Digitized by Google

If the steel discs were turned so that they presented similar poles to each other, they would repel one another. Similarly the two coils will repel one another if they are so placed that the currents in the two are in opposite directions, and the coils are prevented from turning round. The lines of force due to such a pair of coils are shown in Fig. 6.

Since the attraction or repulsion between the coils must be due to the actions of the several portions of the wires upon one another, it follows that wires which are conveying currents in the same direction attract one another, and wires conveying currents in opposite directions repel one another. This also admits of independent experimental proof.

If two wires are conveying currents in directions making an acute angle with one another, the wires will attract each other. If the directions of the currents form an obtuse angle, they will repel each other. If the wires are free to turn they will set themselves so that the currents are flowing in the same direction in each, and they will then attract one another.

It has been stated that the poles of a magnet will tend to rotate in opposite directions around a wire conveying a current. Similarly, a wire conveying a current will tend to rotate

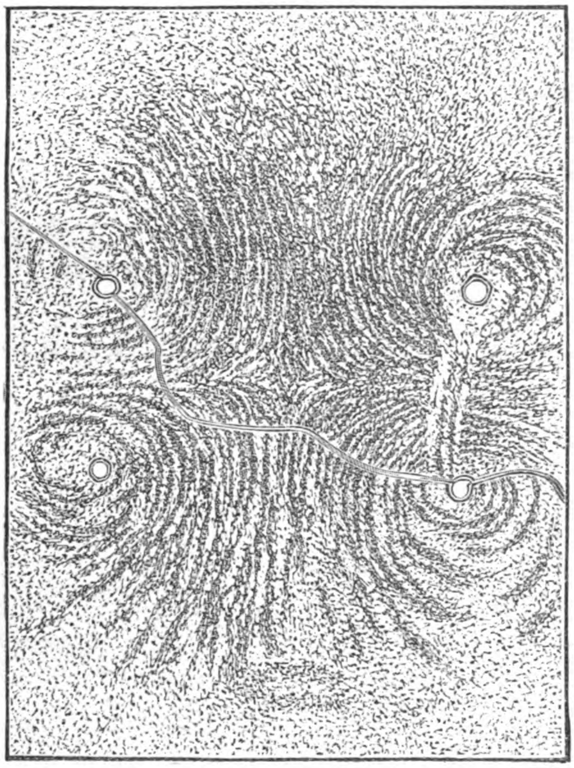

Fig. 6.

about either pole of a magnet, since action and reaction are equal and opposite. Faraday, in 1821, obtained the continuous rotation of a wire about a magnetic pole by sending a current through a wire which could turn about a joint at its upper extremity, while its lower dipped in a circular trough of mercury which surrounded the pole of a magnet. The rotation of a conductor conveying a current about magnetic lines of force can be readily shown by the following contrivance :— A beaker containing dilute sulphuric acid is placed upon one pole of an electro-magnet; a copper plate and zinc plate are connected by parallel wires, so that the zinc plate is vertically over the copper plate, and the arrangement is suspended by a thread within the acid, the copper being near the bottom and the zinc near the top of the liquid. A current flows through the liquid downwards from the zinc to the copper plate, and upwards through the connecting wires. On exciting the magnet the acid will rotate about a vertical axis in one direction, while the suspended plates and wires will rotate in the opposite direction. On reversing the polarity of the magnet the direction of each rotation will be reversed.

(To be continued.)

INCANDESCENT LAMP MANUFACTURE.—II.

BY J. SWINBURNE.

Retort Carbon.

The early workers in the field seem to have used retort carbon sawn into thin strips. The fault was, of course, that the carbons were not of uniform resistance, and the processes of manufacture were too difficult.

Coming down to modern times, we find Sawyer, or Sawyer and Man, decomposing hydro-carbons by heat, and utilising the deposited carbon. They used a thin piece of willow charcoal as nucleus, and deposited a thick coating on it by electrically heating it under such liquids as alcohol and olive oil. The carbon was used as so made, or the deposited carbon was removed from one side so as to expose the willow charcoal, and the charcoal was then scooped out, leaving a sort of crescent sectioned or boat-shaped conductor. This process is fully described in "Electric Lighting," by Sawyer (Nostrand and Spon, 1881), so there is little use in describing it here. Sawyer's lamp was at that time a very primitive apparatus, and his method of making carbons has never come into general use. However, as this has been, and may soon again become a matter of litigation, the point had better not be discussed here.

Carbon deposited by decomposition of such bodies as oil, alcohol, or hydro-carbon, seems to be almost a distinct allotropic modification of that element. Charcoal raised to a very high temperature acquires the same, or almost the same, properties, so these properties no doubt result from the high temperature, and not from the source of the carbon. Among these properties are high electrical and thermal conductivity, hardness, incombustibility below a very high temperature, and inability to occlude much gas.

Carbon deposited by decomposition of hydrocarbons seems always to be nodulous, even if deposited slowly at very high temperatures.

Jameson, of Newcastle, has worked at deposited carbon. His plan was to deposit it inside glazed porcelain tubes, and to turn the carbon conductors out of the resulting carbon tubes, like little piston rings. He abandoned these experiments either because they did not look promising or because his time was too fully occupied in working out his coke process.

If a gaseous hydrocarbon is rapidly decomposed by heat, the carbon is deposited in tufts of fine black hairs. Messrs. Hughes, Maxwell, Rowland, and Chambers have lately been working at deposited carbons. One of their methods is to make these carbon hairs artificially for use in incandescent lamps. These carbon hairs are sometimes produced in great quantities, and of great length, in coke ovens. Either Mr. Cookson or Mr. Jameson gave the writer a box of these carbon hairs to try as lamp carbons in the spring of 1883. Unfortunately, the hairs were too crooked and too uneven and unmanageable for use, and were not tried.

The Cruto lamp is made by heating a very fine platinum wire electrically in an atmosphere of some gaseous compound of carbon. The process is very interesting, but is somewhat difficult, as the platinum must be raised to a temperature very close to its melting-point in order to decompose the gas. The writer has no special experience of this kind of manufacture, so he cannot give any information beyond that already published on the subject. A short account of the manufacture of Cruto lamps has already appeared in the electrical papers. It has sometimes been said that the Cruto lamp is superior to others, because it has a hollow carbon. In the chapters on testing, and on the theory of the incandescent lamp, it will be shown that this reasoning is fallacious. The chief fault in this method of making carbons is that they are of such low specific resistance that a carbon has to be made very long and thin to give, say, fifteen or twenty candles at, say, 100 volts. This lamp, on the other hand, should be very well adapted for low resistance, or series work, as it is difficult to make a carbon by other methods which will take several amperes without being inconveniently thick. The Cruto carbons have a beautiful finish.

Messrs. Boullon, Probert, and Soward have made very thin carbons by a curious process. They pass induction coil sparks between two points in a hydro-carbon atmosphere. This decomposes the hydro-carbon, and builds up a very fine carbon

Digitized by Google

thread. The electrodes are made to recede as the carbon is formed. Some short carbons prepared by this method were given to the writer by Mr. Probert. They were so exceedingly fine, however, that they could not be easily mounted. The extreme fineness also made them unsuitable for anything but lamps of very small candle-power, as it would have taken some feet to make an ordinary lamp, and such a length would not have supported its own weight.

The writer has tried some experiments with the view of depositing carbon on metal wires so as eventually to get rid of the metal, but without success. Fine iron wires were heated electrically in an atmosphere of carbon disulphide. When any part of the wire became red hot it was attacked so vigorously by the sulphur that it fused at that point. Of course, immediately the iron was partially converted into sulphide the resistance at the part attacked increased. The same thing happened when the experiment was tried in an imperfect vacuum. Even if the whole of the iron were converted into sulphide with carbon deposited throughout, there might be difficulty in getting rid by volatilisation or otherwise of the sulphide.

A similar experiment was tried with carbon tetrachloride instead of sulphide, but with no better results. The chlorides of most of the metals are volatile. It would be interesting to see whether carbons could be made by these means, a furnace being used instead of electrical heating.

A great many futile expriments will be described in these articles, because many who would otherwise have thought of the same things and tried them may be saved the trouble, and many may see the causes of the writer's failures, and may, by avoiding them, work out some of the ideas successfully.

Vegetable Carbon of Organic Structure.

Under this head are included carbons made of carbonised paper, bamboo, various grasses, roots, woods, &c., and cotton or linen thread.

There is no doubt that carbons consisting of bundles of partly separate fibres are weak, and that all the carbons in this group are inferior to some other carbons in use. Of course, many of the materials may be partly "parchmentised" or converted into an amorphous substance of the same percentage composition as cellulose, and the more nearly the carbon is made homogeneous the better.

Thin slips of bamboo are used by Edison even now; but the resulting lamps are generally run at a low temperature. These bamboo slips seem harder than most carbons of the sort. They are apparently cut out of bamboo by special tools, and they look as if the carbons had been "treated," or, as it is sometimes called, "flashed," very little.

Carbonised paper was one of the first things tried. Swan appears to have used it first, and Sawyer, Edison, Maxim, and others have followed. The best kind of paper to use is the toughest and densest that can be got. The resulting carbon has a very high specific resistance, and would therefore be useful for high resistance lamps, but unfortunately it is not durable. Maxim used paper which had been carbonised in the presence of a hydro-carbon, and "treated" afterwards. Many of these paper lamps were very durable, and were only slightly inferior to the best amyloid lamps. The methods of testing by which these conclusions were arrived at will be explained in the chapter on testing lamps.

The writer has tried impregnating paper and cotton thread with various things to fill up the pores, and thus make the carbons more solid and less fibrous. Many kinds of gum, several resins, dextrin, starch, &c., are of little or no use.

Very good results may be got by the use of the aniline dyes. Of these, fuchsine is perhaps the most convenient. Fuchsine is soluble in alcohol, but the solution is deceptive, as it is not so strong as it looks. The best solution is got by adding about 10 or 15 per cent. of aniline to the alcohol. Aniline dissolves fuchsine readily, but as it does not dry well, too much will prevent the solution from drying. Methylated spirits may be used instead of alcohol. The paper blanks are dipped in this solution and allowed to dry before carbonising. Lamps made with these carbons are very durable, and the process is very simple, and the carbons can be made by girls. Cotton thread steeped in this solution does not make good carbons. No one who has not tried it has any idea of the difficulty of cutting a lot of paper slips alike. It is absolutely necessary in the commercial manufacture of lamps that the finished carbons should all have the required surface. The Maxim carbons were beautifully cut into the form of an M. Paper cannot be cut uniformly by a bookbinder's knife, as it gives a little under the pressure. A sunken punch and a piece of lead are used for cutting out numbers or stars or such things, but it would be difficult or impossible to cut out a horseshoe groove three inches long and one-fiftieth of an inch broad in the face of a steel punch. Moreover, the blanks could not be got out whole. The converse method of punching the blank into the lead is good so far, but the blank sticks in the lead. The writer tried alloys of various kinds, with the view of floating the blank out by melting the alloy under oil; but the alloys that were sufficiently fusible were so hard that the material was injured in being punched into it.

A method often used is mounting the material on a cylinder in the lathe, and screw-cutting it into a spiral. This method has been patented by Messrs. Jackson, Davidson, and Duncan, and has also been used by other makers. The drawback is that it is slow and troublesome, and that it does not give a flat horseshoe, and the other form, in which the material is bent over into a loop, gives trouble in the processes following, such as mounting and carbonising. It is also more difficult to test this form accurately; the best method is stamping. This will be fully described under amyloid carbons.

Great caution must be observed in the use of aniline dyes. Some of them are very dangerous, as they give rise to blood-poisoning. Aniline itself is also to be handled with great care. Aniline dyes are very penetrating. If a girl is given a couple of ounces of fuchsine solution she gets it over her fingers, probably spills some, and gets it over her clothes and face, and everything she can possibly get at is eventually *couleur de rose.* A reducing agent, such as sodium sulphite, should be supplied to discharge the colour, as it is exceedingly difficult to wash out completely.

Various roots and fibres have been recommended or used; but though they may be more or less hard they are difficult to make all of the same size.

At first sight it might seem as if cotton thread or paper heavily treated would make good lamps. Many of the early Lane-Fox lamps seem to have been made in this way. This method does not give good results, as the deposited carbon is apparently nodulous, and full of minute cracks, and forms a sort of shell over a soft fibrous interior, instead of filling up the interstices and making the carbon solid.

CORRESPONDENCE.

NOTATION, SATURATION, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The arrangement of wires supposed by Mr. Bosanquet can only exist if all the layers are spirals wound in the same direction. In this case the last turn of each layer would have to be secured in some way before the wire is cut off and a new layer begun. When I first adopted iron wire for the core of my armatures, I was fully aware of the theoretical advantages which such an arrangement would present; but I have never attempted to carry it out in practice, on account of the great difficulties and the increased cost of manufacture which it would entail. As far as I know, all dynamo makers who use wire simply lay it on in a continuous length, and in right and left-handed spirals, until the proper depth of core is reached. As a natural consequence the turns must cross each other, and the distance between the centres of two wires is at the crossing equal to the diameter of the wire. It might, however, be supposed that before and after crossing the wires would arrange themselves in the triangular fashion sketched by your correspondent. Perhaps with great care and special appliances it might be possible to produce this. The wires of each layer would then lie for the greater part of the circumference in the grooves between the wires of the layer underneath, and would have to be brought sharp across once in each turn so as

Digitized by Google

to fall into the next groove. At the crossing points there would be formed a ridge along the cylinder, which would throw its surface out of truth, and although it might be possible, with great care, to distribute the ridges of successive layers evenly round the circumference, such a system would entail more labour and loss of time than the extra amount of iron got into the armature would be worth; besides which I very much doubt whether an armature so constructed would run true and be balanced. As a matter of fact the wire is laid on by special winding lathes, which guide it rigidly in right and left-handed spirals, and if you inspect an armature at any stage during the winding you will notice that it presents no ridges, and that the spirals are all even. When finished, the armature is almost mathematically true and perfectly balanced. I think after this explanation Mr. Bosanquet will agree with me that the way I estimate the space filled by iron is correct.

I am not sure whether I quite understand the meaning of his remark regarding the "errors which would arise from the impossibility of securing any accurate geometrical arrangements, or of preventing changes of figure in the section of the wire due to the force used." If he alludes to the reduction of diameter consequent upon the strain in the wire during the process of winding, I would point out that this reduction is infinitesimal, and, moreover, has no influence on the accuracy of the calculation, since the diameter of the wire does not enter at all. If he alludes to any deformation of the coil due to the strain of winding, I think he pays a very poor compliment to the ability of the modern electrical engineer. Surely he must know that dynamos of the present day are not the gingerbread things, held together by tape, wood, and a little glue, which they were ten years ago, and that modern dynamo makers treat this machine in the same way as other engineers treat their work—that is to say, every part is designed with a due regard to the strains it will have to bear. If your correspondent will favour me with a visit I shall show him the gunmetal supporting cylinder on which the iron wire forming the core of the armature is wound, and he will then see that any error in the calculation of area, as far as it refers to a possible deformation, is absolutely excluded. The question of units was thrashed out at the Society of Telegraph-Engineers, and the matter now stands thus: Every scientist of note is opposed to my system of units, and some practical engineers besides myself use them. The society has given me a patient hearing on this question, and since I have had my say I do not think it necessary to refer again to the matter here.

In a letter following that of Mr. Bosanquet, the writer accuses me of attributing but "secondary importance to scientific research' undertaken for the mere sake of advancing knowledge." I need hardly say that nothing could be further from my thoughts. I, in common with every electrical engineer, know how very much we are indebted to the researches of men like Faraday and Clerk-Maxwell, whose discoveries form the basis of all our recent improvements. The question at issue, however, is not the discovery of new laws which may at a future date prove of practical utility, but simply the application of the laws already discovered to practical purposes at the present day; and my contention is that if a man wants to get the credit for such practical application he must present it to the world in a form ready for use by the practical engineer or electrician.—Yours, &c., GISBERT KAPP.

Wimbledon, December 8, 1886.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Considerable perturbation in the minds of not a few scientists seems to have been caused by the arbitrary system of magnetic measurement introduced by Mr. Kapp.

I fail to see either the difficulties which are supposed to be introduced, or any want of proper precedent for this new departure. Mr. Kapp's object is avowedly to facilitate matters in handling the figures, and by common consent 10^8 absolute units are taken to one volt for this very same purpose. Adopting Mr. Kapp's symbols the equation for the E.M.F. in the coils of the armature is, in absolute measure,

$$E a = Z . N t . n,$$

where Z is taken in absolute lines, and n stands for the number of revolutions per second. In order to diminish the numerical value of $E a$ we introduce the volt, and say

$$E a = Z . N t . n . 10^{-8},$$

or, taking M to equal the number of lines per *unit of area* of iron in the core, and a its cross section,

$$E a = 2 M a . N t . n . 10^{-8}.$$

Now, all that Mr. Kapp does further than this is to multiply n by 60, making it to mean revolutions per minute instead of per second, and then, finding the numerical value for M still inconveniently large, to multiply the factor 10^{-8} by 100, making it 10^{-6}, M being thereby numerically reduced to $\frac{1}{6000}$ part of its original value, the true value of the unit line, on the other hand, being increased by 6,000 times. As a matter of fact, and I speak from experience, the above measure is far more convenient for the use of practical men than the absolute measure, especially in dynamo design, and herein lies the value of all Mr. Kapp's work. A practical man himself, he gives us theory in such a guise that we can all make use of it, and whosoever may or may not have had prior notions of a similar character to those of Mr. Kapp on magnetic saturation, he alone has given to dynamo engineers, in a language they can understand, the means of assigning correct proportions to the several parts of the magnetic circuit.—Yours, &c., GUY C. FRICKER.

Battersea Foundry, Battersea, Dec. 4, 1886.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Bosanquet has fallen into a not uncommon error in supposing that "when wire is wound, the coils of each layer bed in the hollows of the layer below." This mistake was made some time ago at a meeting of the Telegraph-Engineers, when it was seriously proposed to lay a bare wire in the wasted space between the coils.

A moment's consideration shows that in winding a bar the layers are alternately right-handed and left-handed, and that during a part of a turn a wire will tend to lie in the hollow, and in another part it will ride on the top of the wires of the lower layer. As a matter of fact, the number of *layers* per inch of a given wire turns out in practice to be identical with the number of *turns* per inch when wound on a bar.

In armature winding, when there is more than one layer, it is obvious that the wires cannot lie as Mr. Bosanquet imagines, unless there are an equal number of turns in each layer, the practice generally being to get in as many turns as possible, so that each layer may be full.

Mr. Kapp, as a dynamo maker, is, of course, fully aware of this.—Yours, &c., ALEXANDER P. TROTTER.

Bull Green Works, Halifax, Dec. 7, 1886.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is curious that after my letter of last week I should myself have to apologise for a clerical error in a paper of mine, due to mixed units. In paragraph 3 of my paper on "The Tension of Lines of Force," reprinted from the *Phil. Mag.* in your last issue, page 83, the magnets are said to be each ·526 centimetre in diameter. This should be ·526in. The calculations are all right, but the clerical error crept into the description. We measure such diameters with an English watch maker's gauge, and our form of reduction provides for the computation in centimetres. But we measure greater lengths direct from a metre scale, using in each case such instrument as is most convenient. This is an excellent illustration of the liability to mistake involved in the use of mixed units, although the mistake is not of great importance.—Yours, &c.,

R. H. M. BOSANQUET.

St. John's College, Oxford, Dec. 6, 1886.

DYNAMO TESTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In his article on "Testing Dynamo Machines," published in your issue of December 3, Mr. Swinburne, referring

Digitized by Google

to the recent tests of the efficiency of the Edison-Hopkinson dynamo, says :—

"The power supplied to the two machines separately excited at no load is, according to *The Electrician* for March 12, 1886, 7·169 horse-power, or 5,350 watts, say 2,675 per machine. We thus have for the generator :—

Stray power	2,675
Loss in armature	1,360
Loss in magnets	716
Total loss	4,751
Output	40,600
Power supplied by belt	45,351

Commercial efficiency 88·2 per cent.

"This determination does not agree with those of Drs. Hopkinson. They make out the commercial efficiency of the dynamo to be 93·23 per cent. Unfortunately the published tests of Drs. Hopkinson discrepe too much to be of use. The power spent on turning the armatures with no currents is given as 7·169 horse-power, and when the full current is taken it apparently drops down to 2·22. The 93·23 per cent. is calculated from the latter figure ; but what becomes of the odd, the very odd five horse-power ?"

In these remarks Mr. Swinburne, not understanding the significance of the figures he has quoted, has fallen into grave error, which, though obvious, calls for correction, especially as it is the repetition of a mistake made by Mr. Kapp in dealing with the same figures in his article in the *Engineer*, March 5, 1886, which was corrected in the subsequent issue of the same paper, the correction having apparently escaped Mr. Swinburne's attention. Mr. Swinburne has assumed that the zero of the dynamometer scale employed was the point at which the index would stand when the machine was at rest. Such, however, was not the case, as the scale was placed arbitrarily, and all experiments made by taking the difference of two readings, the one when the machines were working with a known load and at a known speed, and the other when the machines were running at the same speed without load and with the magnets unexcited. The dynamometer reading first given is, therefore, the zero of the dynamometer scale, neglecting the friction of bearings and bending the belt, which was determined by separate experiment subsequently described at length in the same article. Thus, the odd 5 horse-power exists only in Mr. Swinburne's imagination. If Mr. Swinburne will refer to the actual figures published by Dr. Jno. Hopkinson and myself (*Philosophical Transactions* of the Royal Society, Part I., 1886), instead of referring to an unsigned article, for which we were not responsible, he will more clearly see that the mistake is his and not ours, and that our figures are perfectly accordant and precise within ¼ per cent., and prove beyond all cavil a commercial efficiency of over 93 per cent. exclusive of friction, and 91·9 per cent. when the mechanical loss, not only of the friction of the bearings, but also the loss by bending the belt round the dynamo pulley and the pulleys of the dynamometer, is included.

Nor is a matter of nearly 4 per cent. in efficiency a point of small consequence, for it represents in a dynamo of this size about 2¼ horse-power, which may be valued at £22. 10s. per annum, and therefore, reckoning 10 per cent. depreciation and 5 per cent. interest, such a dynamo of 91·9 per cent. efficiency is worth to the purchaser £150 more than one of 88 per cent. efficiency.—Yours, &c., EDWARD HOPKINSON.

Salford Ironworks, Dec. 6, 1886.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following extension of my method of testing dynamo machines will, I believe, be found applicable to well designed machines, in which the distortion of field by the armature current is small. The two machines are connected by a belt or otherwise, field-magnets separately excited, speed kept at what it is intended to work the machines subsequently :—

1st. Both machines excited, no current taken from generator. Let W_1 be power supplied to motor, w_1 power absorbed in heating armature conductor.

2nd. Generator unexcited. Let W_2 be power supplied to motor, w_2 power absorbed in heating armature conductor.

3rd. Generator excited and supplying current. Let W_3 be power supplied to motor, w_3 power absorbed in heating armature conductor, W_4 power given out by generator, w_4 power absorbed in heating its armature conductor.

4th. Reverse the machines, making motor generator, and generator motor, and take similar tests. Let W_1^1, w_1^1, &c., be the results.

5th. Run each machine singly as a motor. Let W_5 and W_5^1 be the power applied, w_5 and w_5^1 that absorbed in heating armature. At this speed and strength of field let U be the loss by undirected electrical energy in machine 1, U^1 in machine 2 ; F and F^1 be the respective losses by friction, air-pumping, &c. ; B the loss absorbed by belt.

Then we have

(1) $W_5 - w_5 = U + F$,

(2) $W_5^1 - w_5^1 = U^1 + F^1$,

(3) $W_2 - w_2 = U + F + F^1 + B$,

(4) $W_2^1 - w_2^1 = U^1 + F + F^1 + B$,

(5) $W_1 - w_1 = U + U^1 + F + F^1 + B = W_1^1 - w_1^1$,

(6) $W_3 - w_3 = W_4 + w_4 + U + U^1 + F + F^1 + B$,

(7) $W_3^1 - w_3^1 = W_4^1 + w_4^1 + U + U^1 + F + F^1 + B$.

From these equations all the factors may be determined with many checks. Should the values of $U_1U_1^1$ and $(F + F^1 + B)$ found from equations (3) (4) and (5) be found to suit equations (6) and (7), U and U^1 may be taken as constants for any load.

This is what Mr. Swinburne proposes in your last week's issue.

With some machines, at any rate, this does not appear to be the case, as, indeed, might be anticipated, and in this case by varying the load on the generator the approximate law of variation of U and U^1 can be determined. The efficiency, either absolute or commercial, for any load on the machine can then be calculated.

I have applied this method to several machines, and have been surprised at the closeness of the results.

It is absolutely necessary that the speed and adjustment of brushes be closely attended to.

The inefficiency caused by a wrong adjustment of brushes is hardly, I think, realised, or the fact that the absolute efficiency of a good machine certainly increases as the load on it is increased.

I do not agree with Mr. Swinburne in his preference for high-speed machines, but will not enter upon this question now.—Yours, &c., P. CARDEW.

Chatham, 8th Dec., 1886.

WELDING BY ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : We notice in your issue of the 3rd that Mr. Radcliffe Ward claims priority in welding by electricty in the year 1884. We beg to say we have used this method since 1881 for welding or soldering the lead connections on secondary batteries ; and prefer it to any other way, and doubtless other secondary battery makers have done the same. It makes a clean joint and good contact; little skill is required in manipulation.—Yours, &c., H. THAME AND CO.

TELEPHONY.

English technical publications are often searched in vain for indications of progress in certain branches of applied electricity. So far as this country is concerned, progress seems limited to apparatus connected with electric lighting. We use the term seems advisedly, because we can hardly imagine that improvement is really wanting, but attribute the general ignorance of such improvements to the peculiar position which telegraphy and telephony hold here. That the telegraphic system of England is superior to that of any other country is a fact we readily admit, but we maintain that the public, who really support the system, would like occasionally to be taken more into the confidence of the authorities. They would like to hear of some of the marvellous deeds that are constantly being done, instead of waiting for the next great debate. What, for example, constitutes the ordinary number of words transmitted for newspapers in a day throughout the whole country? A cable is laid here or repaired there; but it is only by accident that this work is mentioned outside official reports. The American and other technical journals from time to time record improvements in telegraphic apparatus, while in England the improvements are made without any such record. The service is benefited all the same whether published or not; but a greater interest is taken in the work, and less soreness felt among inventors and their friends if publicity be given to these improvements.

When we consider the position of telephony in England the case is altogether different. Day by day the capital account is increasing, day by day the public is finding out what a great convenience a good system of telephony is, and yet in regard to improvements English telephony is as silent as the grave. We ask with all due humility whether the system is perfect? Turn to the *Transactions* of the Society of Telegraph-Engineers and attempt to find information on telephony. The attempt is in vain. Year after year goes by, and the *Transactions* contain no indication that there exists a branch of applied electricity of increasing importance, and in which so large a capital is employed. Once, we believe, the magnates of the telephone world opened their hearts and invited various gentlemen to see the working of a new piece of apparatus "brought from America.' We ask these magnates what they have done to foster improvements by their own staff? We ask the members of the staff of the largest company if almost every suggested improvement has not been pooh-poohed, and, further, is it not a fact that those members of the staff who show signs of interest in their work, and a desire to perfect details, are sooner or later found "seeking a situation?"

The users of the telephone complain of its imperfections, thus showing that the system is imperfect, and yet no one seems to have any practical interest in improving it. So far as we know, more has been done by the smaller companies than by the United Company. In the North many towns are being rapidly connected by trunk lines, and again is this the case in the West. Soon Bristol will talk with Cardiff, and in Lancashire all Cottonopolis will be connected; and so in other districts, such as around Birmingham and Leeds. Surely, we may ask if among all those persons connected with telephony there is not one who dares stand up before the Telegraph-Engineers and give an account of the work? We might suggest as a valuable contribution to the literature of telephony a paper on "The Faults as Reported in London in One Month." Much, very much, may be learned from failures, and above all from the failures during the infancy of a business.

Perhaps those who have read these desultory remarks thus far will have come to the conclusion that we are writing more for ourselves than for the general members of the profession. To this we reply that up to the present time we have given more practical telephonic information than any other publication whatever, whether in the form of a book or periodical—that we could probably give quite a startling paper upon the subject suggested, but it would not be from information supplied by the companies. Our intention is to hint that valuable information might be given by themselves rather than obtained from indirect sources. It seems to us, also, that the Society of Telegraph-Engineers should bestir itself from time to time to get papers of a technical character which would enlighten us somewhat upon the question of "progress in telephony."

THE SOCIETY OF TELEGRAPH-ENGINEERS. PRESIDENTIAL ELECTION.

The Annual Election of the officers of this Society took place last evening, with results the particulars of which are given below. Since our last week's issue ample evidence has reached us justifying the course we have pursued with regard to this Election. Our correspondence columns testify to the feeling aroused among a large section of the London members by the conduct of the Council, a feeling which has become more widespread in consequence of the course which some friend or friends of the Council's nominee for the presidential chair have seen fit to take in supporting him. A biographical puff of the true elec-

Digitized by Google

tioneering type had been sent round to the electors, and carried to all appearance the *imprimatur* of the Society. We did not for a moment believe that it emanated from that source; but we cannot help regarding it as confirming our view that the Council itself was to the very last divided on the main question. Had it been otherwise there would have been no apprehension as to the security of the Council's nominee, and this remarkable document would not have been issued on his behalf.

Turning to the business of the evening, we have first to observe that the cheers which greeted Mr. Almack's question, and the still heartier applause which followed the President's answer, sufficiently indicated the feeling of the members with reference to the indignity put upon them by the issue of the document above referred to. The Council, as such, had nothing to do with its publication; and several of the Council members present declared they had not even seen it. We need hardly remark, however, that the ill-advised action of the candidate's friends would not of itself have elicited this manifestation of disapproval. Evidently a considerable number of the members present had made up their minds to a certain line of action, and resented the attempt to influence a decision already arrived at. Nothing, short of an adverse vote, could have demonstrated more conclusively the fact that, whether right or wrong in the recommendations we have made in this journal, we have had a considerable following of sympathisers.

But this is a trifle compared with the incident which followed. The voting papers having been deposited in the box, the scrutineers took charge of it, and retired at the usual hour—half-past eight o'clock. Usually on these occasions their work is done in a little over an hour; but although the scrutineers had been doubled in number, ten o'clock struck, half-past ten, and still they did not appear. Speaker after speaker followed each other, in order to fill up the time, discussing at extreme length questions which, although sufficiently interesting of themselves were not what the meeting was waiting to hear. Only at twenty minutes to eleven was the result made known. It was suggested, as an explanation of this unprecedented delay, that the list of alternative names to be selected from was longer than on previous occasions. We leave it to our readers to judge whether this circumstance alone afforded the true explanation.

The following is the list of officers elected:—

President:
Sir Charles T. Bright, M.Inst.C.E.

Vice-Presidents:

Edward Graves	J. Hopkinson, M.A., D.Sc., F.R.S.
Colonel Sir Francis Bolton.	William Crookes, F.R.S.

Ordinary Members of Council:

William T. Ansell, F.R.G.S.	Alexander Siemens.
Prof. W. E. Ayrton, F.R.S.	Augustus Stroh.
E. B. Bright, M.Inst.C.E.	Major Charles F. C. Beresford, R.E.
R. E Crompton, M.Inst.C.E.	Dr. J. H. Gladstone, F.R.S.
J. A. Fleming, M.A., D.Sc.	H. R. Kempe, A.M.Inst.C.E.
Prof. G. Forbes, M.A., F.R.S.E.	Sir David Salomons, Bart, M.A.

Associate Members of Council:
J. Brockie. Colin Brodie. C. H. B. Patey, C.B.

Honorary Treasurer:
Edward Graves.

Hon. Secretary:
Colonel Sir Francis Bolton.

Hon. Auditors:
W. Blundell. | F. C. Danvers.

Hon. Solicitors:
Messrs. Wilson, Bristowe, and Carpmael.

South of England Telephone Company.—The letters of allotment for the new issue of 10,000 Preference Shares in this Company were posted yesterday.

ELECTIONEERING AND SCIENTIFIC SOCIETIES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Since noticing your announcement of the forthcoming meeting of the Society of Electricians on Thursday next, and receiving from the secretary a ballot paper as usual, I have received with reference to the ballot an anonymous puff of the president-elect.

I write this to ask you to use your influence to prevent further disgrace to our hitherto respectable society by the recurrence of any such undignified proceeding.

It is also an insult to the president-elect and to the electors to suppose that his deeds are not household words amongst us and his genial presence a familiar reality.—Yours, &c.,

Edward Almack.

Fawley, Mount Nod-road, Streatham, Dec. 6th, 1886.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In reference to your leader of the week before last I think that the thanks of all the members of the S. T. E. are due to you for it.

Prof. Forbes's eulogy on the council candidate will no doubt have had much weight with those members who, living in the country, are unable to attend the society's meetings. Such members can generally only blindly follow the recommendations of the council, or at most judge by the work which their nominees have done.

Those members, however, who are in the habit of constantly attending the meetings have the evidence of their eyes and ears to go by as to the suitability of any candidates for office. I have the pleasure of knowing a considerable number of these London members, who are engaged in all branches of electrical work, and have spoken to some twenty or thirty of them on the subject. With only one exception (a friend who rarely attends, and had returned his paper without alteration) they are all voting for the candidate suggested by *The Electrician*.—Yours, &c., Unus pro Permultis.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Having travelled a good deal lately, and my papers having been pretty heavily handicapped, your July 23 did not come up to me till to-day, when I saw the "Cuttriss Patent Siphon Vibrator" article. With some surprise I read that the principal part of the *invention* is the adjustable vibrator at the right of the illustration.

In the early part of May, 1885, I made bold to send to the Society of Telegraph-Engineers a paper on a mode of increasing the speed and definition of signals with Sir Wm. Thomson's permanent magnetic recorder, which was printed in pamphlet form by them. At this time my siphon vibrator had had 10 months' continuous trial, and was, I have good reason to believe, the first in operation, and considerably added to the speed of the line it was used on.

Mr. Cuttriss may not be aware of this; in fact, the refreshing innocence with which the "Inventor" heralds the right hand part of the illustration would naturally lead some people to believe him to be the father of it; but

"Mony a man rocks anither man's bairn," &c,

In its adaption to the mouse-mill type of recorder Mr. Cuttriss has gone out of the way considerably to attain his end, making the alterations much more costly than necessary; and on a line where really delicate adjustment is needed would undoubtedly show to disadvantage.

There are many ways of obtaining the same end with the *assistance of a vibrator*; but I really think Messrs. Cuttriss, Dickenson, and other adapters should be satisfied with that part of their illustrations which strictly belongs to them.

Apologising for taking up so much space.—Yours, &c.,

G. F. Pescod.

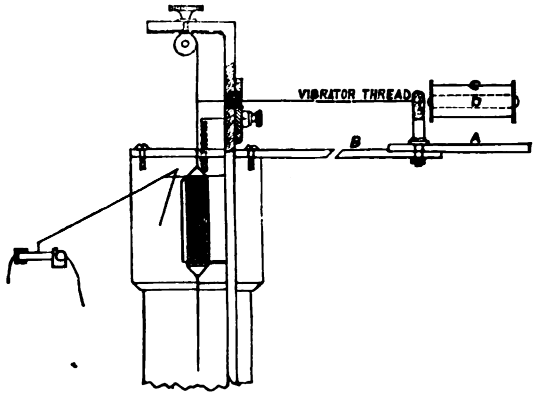
San Juan del Sur, October 18th, 1886.

Mode of Increasing the Speed and Definition of Signals with Thomson's Permanent Magnet Siphon Recorder.

Thinking it might be of interest to some of the members of your society, I beg to send you the following account of a simple and very satisfactory arrangement for increasing the

Digitized by Google

speed and definition of signals, with Sir W. Thomson's permanent magnet recorders, without electrification of the ink:—These recorders are admirable and economical for lines of 800 to 1,000 miles, but after that the friction between the siphon and paper begins to tell very much on the clearness of the signals. We have succeeded in reducing the friction to a minimum by vibrating the siphon very quickly, using a small make and break similar to that generally employed on induction coils. As will be known, in these instruments the siphon is rigidly fixed to the suspended signal coil; therefore, to obtain vibration of the siphon, the whole suspension must vibrate. This is obtained by leading a fibre from the hammer of the make and break to the thread supporting the signal coil, and fastened to it about half an inch from the top. On the battery being applied, and the right tension given to the threads, the action is found to lift the siphon rapidly up and down, and the same fine line is obtained as in the mouse-mill recorders. The paper is adjusted so that when the vibrator is working the siphon is from one-sixteenth to one-eighth of an inch clear from the paper; the vibrator, being placed a foot from the magnets, is not affected by it, and can be cut off and started at will. The arrangement is placed at the back of the instrument, a hole being drilled in the centre-piece to pass the vibrator thread to the suspension thread.



A Movable in the same line as thin board B. C and D also same direction.

To regulate, slacken vibrator thread by moving A towards magnets, then slowly reverse movement, drawing vibrator away from magnet till siphon vibrates steadily up and down. Care must be taken to have the signal coil quite clear from the magnets on both sides, or the line will be blurred when vibrating the coil, owing to its not having sufficient room. Should the vibrator not start well, it will most likely be found influenced by the large magnet, and should be placed a little further off. It is necessary to use condenser to prevent sparking at contact. The best siphons are long fine ones with only two bends.

It has been in operation on the longest section of the Central and South American Telegraph Company, from San Juan del Sur to Santa Elena, in Ecuador, nearly 1,600 miles, for eight or nine months, with excellent results, seldom requiring adjustment, and from the appearance of the signals, it could not be told that the coil was under vibration. The line of ink is perfectly even; it also has the advantage of permitting the use of much finer siphons than under the usual mode.

Not having heard or read of anything being done in this direction previously, I trust my experiment may be something new.

San Juan del Sur, Nicaragua, May 7th, 1885.

LITERATURE.

Theory of Magnetic Measurements, with an Appendix on the Method of Least Squares, by F. NIPHER, A.M., Professor of Physics in Washington University. [Van Nostrand, 1886.]

This book is intended by the author to be a guide in the "practical details of a magnetic survey," and as far as this limited range is concerned it admirably fulfils its object. The mathematical work is simplified by making the usual assumptions which enable the higher analysis to be dispensed with, and when this method is impossible the results only of the more abstruse investigations are given. Thus, in discussing the "pendulum law," the assumption is made that the arc of vibration is infinitely small, and the periodic time is neatly deduced in an elementary manner; but in correcting actual vibrations to this ideal case the formula of reduction is given without proof. Specimen tables, worked out in detail, illustrate the more important computations necessary for reducing the observations; but we regret to notice that the foot-grain-second system of units is used. Surely it is quite time that the C.-G.-S. system should be universally adopted for the highly scientific work of a magnetic survey. The magnetometer figured (apparently taken from a trade catalogue) is less convenient than the Kew pattern, as there is no arrangement for determining the astronomical meridian, thus necessitating the use of a separate transit instrument. The appendix on the method of least squares will be found useful to those who are unable to consult more ambitious works on the subject; for ordinary work, however, we much prefer graphical methods for smoothing out the observational errors.

As we have already said, this volume treats its limited subject well, but we must strongly protest against the increasing practice, which it exemplifies, of setting forth on the title-page much more than is included in the subject matter of a book, and thus, no doubt unintentionally, misleading purchasers or library readers. The work before us is *not* an exposition of the "Theory of Magnetic Measurements" in the sense in which modern electricians understand the term. There is absolutely no mention of the measurement of intense magnetic fields, of the magnetic quality of iron, or of numerous other measurements which are of such importance to the workers of to-day. True, the first paragraph of the preface corrects the error, but as publishers seldom, and librarians never, include extracts from prefaces in their catalogues, the adoption, whenever possible, of correct titles would lead to much saving of valuable time and cause less irritation to the hard-pressed worker. In this instance the "Theory of Magnetic Surveys" would be such a title.

Lives of the Electricians: Profs. Tyndall, Wheatstone, and Morse. First series, by WILLIAM T. JEANS. [London: Whitaker and Co.; and George Bell and Sons, 1887.]

Our first thought on looking at the names in this opening series was that the selection hardly represented the electricians; but after glancing through the life of Tyndall we felt that on no account should it have been left out—rather, perhaps, that the title of the book might be changed to accord more closely with its contents. Reid's memoirs, published in America in 1879, entitled "The Telegraph in America, and Morse Memorial," deals very largely with the life of Prof. Morse, and is, perhaps, the best known book of its kind; but it is written more for American than for English readers, and will very well bear being supplemented by such a biography of Morse as we find in these pages. Of Wheatstone no adequate notice in this form has previously appeared; and there is a natural fitness in bringing the two great telegraphic personalities into juxtaposition within one and the same volume. Motives of a different kind have no doubt caused the name of Tyndall to appear first on the list of this series. He is an eminent man of science, who has gained the popular ear, partly, at least, by his public lectures on electricity. As a rule there are some obvious objections to writing the biographies of men still living, but no exception can be taken to Mr. Jeans' work on the score of excessive adulation. The

Digitized by Google

narrative is a plain statement of facts, which of themselves are the highest tribute the author could pay to the subject of his memoir. Prof. Tyndall's career is sketched from his childhood down to his retirement from the position of scientific adviser to the Trinity House Brethren in 1883. Quite apart from his connection with electrical matters—which does not date very far back—Prof. Tyndall's life is a most instructive and interesting one, being that of a self-made man, who has attained to the highest distinction not only in the field of science, but as a master in the province of letters. An appreciative account of the late Prof. Wheatstone follows, and is of especial interest just now when the jubilee year of the electric telegraph is impending, and the question of its invention is one that is sure to be much discussed. Mr. Jeans settles this disputed point in favour of his hero, as was to be expected; but we cannot complain of his partiality, seeing that the fresh evidence he adduces on disputed points of history in this relation certainly makes for his view of the case. Whatever his merits as an electrician, Wheatstone was, without doubt, one of the most ingenious mechanicians that ever lived, and his name for all time will be associated with the introduction and practical development of electro-telegraphy. America had its Wheatstone, too, in Prof. Morse, whose name is closely identified with the earliest telegraphs in that country. The struggles and disappointments of this talented electrician are well described in these pages, and ought to serve as a permanent lesson of encouragement to every despairing inventor. We could have wished that Mr. Jeans were a little more liberal with his dates, so that any reader using the volume as a book of reference might know exactly where he is, or more correctly *when* he is; but in other respects these memoirs are carefully compiled, and, what is of equal importance in these days, attractively written. Merely as a book to read, "Lives of the Electricians" will amply repay the outlay upon it, both of time and money.

We feel it necessary, however, to mention that there are in this work several technical blunders, which would have been avoided or corrected had it been written by a professed electrician. Perhaps the worst of these is on page 130, where a cup of mercury is described as "a non-conductor." This is probably a typographical error; but not so the mistake which occurs in the descriptions of the experimental demonstration of Faraday's discovery of the electro-magnetic rotation of the plane of polarisation, and others of a similar kind.

BRITISH ASSOCIATION, 1886.

The following papers marked * were contributed to the late meeting of the British Association on various subjects connected with Electrolysis.

ON THE EMPLOYMENT OF ALTERNATING CURRENTS FOR MEASURING LIQUID RESISTANCES.*

BY MM. BOUTY AND FOUSSEREAU.

The authors criticise the employment of alternating currents employed by Kohlrausch and many others in the hope of diminishing the effect of polarisation. They point out that self-induction in the resistance box is fatal to silence in the telephone [naturally], and only succeeded in getting good results when they replace wire in their bridge by liquid resistances, describing for this purpose a libuid rheostat. Even thus, however, they hardly get concordant results when they try to apply the method to extremely weak solutions.

ON MECHANICAL AND THERMAL EFFECTS ACCOMPANYING ELECTROLYSIS.*

BY M. BOUTY.†

A series of short memoirs have been published by M. Bouty in the *Journal de Physique* on a branch of the subject not very immediately connected with that which at present concerns us. I had occasion to refer to part of them in a communication on the seat of E.M.F. in the voltaic pile. (*See* "B.A. Report," 1884., pp. 492 and 513, or *Phil. Mag.*, Vol. XIX. 1885, pp. 189 and 343 to 350.)

The references to them are as follows:—

1. *On some mechanical and thermal effects accompanying electrolysis* (*Journal de Physique* 1879, T. VIII. pp. 289 and 341).

2. *Thermo-electric and electro-thermic phenomena at contact of metal and liquid* (1880, T. IX. p. 306).

3. *On the contraction of galvanic deposits, and its relation with the Peltier phenomenon* (1881, T. X.)

In the first of these papers metals are deposited on silvered thermometer bulbs and the mechanical compression of the different deposits studied, Wertheim's results in elasticity being applied to them.

The effect of heat on such metallised thermometers is also discussed.

Metallised thermometers are then used as electrodes to examine the changes of temperature which occur while various ions are being liberated. During the electrolysis of $CuSO_4$ or $ZnSO_4$ the anode is slightly warmed, the cathode slightly cooled; inverting the current cools the new cathode distinctly. Electrolysing dilute H_2SO_4 with platinum coated thermometers, the anode is quite warm, the cathode scarcely at all. This is the permanent effect. Inverting the current cools the old anode, sometimes $\frac{1}{6}$ degree below the temperature of the surrounding liquid. The effect can be repeated seven or eight times, although with decreasing intensity, if one takes care to stir the liquid between the inversions.

Replacing H_2SO_4 by HCl the permanent effect is very small, but both poles heat strongly at each inversion. With $PtCl_4$ one observes at each inversion a cooling of the old anode and a heating of the old cathode. In every case examined anode is hotter than cathode in the permanent state.

In the second paper, metal liquid junctions are warmed and cooled alternately, so as to give thermo-electric currents, the E.M.F. of several circuits being measured. An attempt is then made to measure absolutely the coefficient of the Peltier effect at these junctions when a current passes, a method suggested by Maxwell ("El. Electricity," p. 146) being used. The result is that the author believes the effects to be purely physical, without known relation to the heats of combination or the latent heats of solution, but connected exactly with the thermo-electric forces of couples corresponding. The thermo-electric laws of Sir W. Thomson are believed to apply without modification. Chemical effects are regarded as disturbances producing parasitic heats.

In the third paper, the author reconsiders the contraction of galvanic deposits in the light of the Peltier effect, and comes to the simple and satisfactory conclusion that the two phenomena are immediately connected. Each envelope being deposited at a rather higher temperature than it is able afterwards to maintain, a state of compression naturally results. This view he sustains by experiment.

CONTRIBUTION TO OUR KNOWLEDGE OF THE ACTION OF ELECTROLYSIS ON AN ELECTROLYTE (BEHAVIOUR OF JELLY).*

BY SVANTE ARRHENIUS.

From numerous researches of physicists† it has been held as proved that resistance to the passage of an electric current undergoes the same variations as the internal friction—*i.e.*, that both increase or decrease simultaneously. This view is based on a considerable number of data regarding the conductivity of salts in aqueous solution. To obtain further knowledge on the subject it was necessary to test the action of solvents other than water. This has been done by C. Stephan,‡ who investigated the behaviour of alcoholic solutions, and found only an analogy between electric resistance and internal friction, but not complete proportionality; and this has been

* *Journal de Physique*, 2e sér. September 1885, T. IV.
† Brief abstract, by Oliver Lodge.

* Translated from *Kongl. Vetenskaps-Akademiens Förhandlingar*, 1885, No. 6, Stockholm. By Professor W. Ramsay.
† Among others G. Wiedemann; a detailed description of the work of others is to be found in his *Electricity*.
‡ Wiedemann's *Annalen*, 1882, XVII., p. 673.

Digitized by Google

confirmed by other observers.* That proportionality exists, except in some exceptional cases considered by Stephan,† cannot be held. Unfortunately Stephan has only investigated alcoholic solutions containing from 0 to 70 per cent. of alcohol—*i.e.*, those of which the internal friction is greater than that of water. Had he investigated solutions richer in alcohol, he would doubtless have found that an alcoholic solution of a salt has less conductivity as the corresponding more aqueous solution, in spite of the former having less internal friction than the latter. This has been clearly proved by Hittorf's work,‡ and has been completely confirmed by Lenz's§ investigations, although Lenz's work was not directed to that point. I subsequently found on conversing with Prof. Ostwald, of Riga, that he, like myself, disbelieved in any connection between internal friction and resistance, and he proposed that I should undertake the investigation of which an account follows. From a paper by H. de Vries‖ it follows further that the rate of diffusion of a solution of salt is nearly independent of internal friction; a result which Graham's experiments clearly indicate. Lastly, Long's¶ work shows that the rate of diffusion of an aqueous solution of salt is nearly proportional to its conductivity, whence it follows with high probability that the resistance must be nearly independent of internal friction under similar conditions. And should this prove to be true, the whole of our knowledge of the process of electrolysis would be much simplified.

The method of investigation was that proposed by Kohlrausch and Nippoldt.**

The resistance vessels were of the same form as those I previously used. The platinised platinum terminals were 15·5 mm. apart, the diameter of each was 25·6 mm., and through each passed a glass tube 9mm. in diameter. The solutions investigated were solutions of sodium chloride, zinc sulphate, and copper acetate, in pure water, and also in water in which had been dissolved 4·2 per cent. of commercial gelatine.

The proportions taken were : (*a*) 20 cc. of the salt solution diluted to 25 cc. with water ; (*b*) 20 cc. of solution, in which 1·05 gram gelatine was dissolved, diluted to 25 cc. The gelatine solutions were tolerably fluid at 30°, at 25° very thick and syrupy, at 24° the traces of fluidity were extremely small, and at 23·5° the whole had jellied.

The internal friction was determined by Sprung's†† method for the gelatine solution containing 4·2 per cent. of gelatine, and was found to be : at 30·5° C. = 2,271, at 27·7° C. = 2·889, the internal friction of water being taken as unity at 0°. At 24° the internal friction was infinitely great, *i.e.*, the solution had gelatinised and blocked the capillary tube. At corresponding temperatures the internal friction of water is at 30·5°, 0 4475 ; at 27·7°, 0·4547 ; and at 24°, 0·5171. The internal friction of the employed weak salt solutions can only have differed but very little from these numbers.

The distilled water showed a resistance of 60,000 ohms, while the gelatine solution averaged 300 ohms. It was therefore considered unnecessary to introduce a correction for the conductivity of the distilled water present. Now, as it is known that all organic substances which do not possess well-marked acid, basic, or salt-like properties have extremely small conductivity, it may be concluded that gelatine also, if free from salts, should manifest great resistance, and the high conductivity of the gelatine is evidently due to the salts which it contains.

The gelatine solution was warmed in a water bath to 35° C. Simultaneous measurements were made of temperature and resistance. As the water cooled the former fell, while the latter slowly rose.

The following table shows in the first column the observed temperatures, and in the second the resistance in British Association units. From these data the conductivity was

* E. Wiedemann has proved this to be the case with solutions in glycerine (Wiedemann's *Annalen*, 1883, p. 20).
† Stephan's figures do not exhibit this proportionality. The ratio is not a constant one.

The results with the gelatine solutions to which salt had been added are given in the Tables on next column.

Here it is evident that the conductivity alters only uniformly with temperature, for had this been otherwise great variations in the neighbourhood of 24° should have been noticeable, for the internal friction increases about that temperature from a moderate value to an infinitely great one. But no sign of such a sudden variation can be deduced from the above figures. The calculated values of the coefficient of temperature for gelatine solution are

Gelatine solution.	Sodium chloride.	Zinc sulphate.	Copper acetate.
0·0281	0·0244	0·0243	0·0248

and for aqueous solutions

	0·0238	0 0234	0·0213

Those for gelatine solutions are generally somewhat higher than for the corresponding aqueous solutions, but the difference is unimportant. It it be assumend that the coefficient of temperature for infernal friction and conductivity is the same for aqueous solutions, this cannot be extended to gelatine solutions, for which the temperature-coefficient of internal friction must evidently be infinity (inasmuch as the coefficient of conductivity never exceeds 0·03). If the conductivity of pure aqueous solutions at 17·8°, which are very mobile, be compared with that of gelatine solutions of 4·2 per cent. containing the same amount of salts, which are solid at 24°, the following table results :—

	Sodium chloride.	Zinc sulphate.	Copper acetate.
Aqueous solution......	250·6	169·6	159·9
Gelatine solution	205·6	140·3	134·2
Difference...............	17·9 per c.	17·3 per c.	16·1 per c.

The gelatine solution has accordingly about 17 per cent less conductivity than the corresponding aqueous solution. The found difference of 17 per cent. is not of the magnitude which might be expected if internal friction had really the effect usually attributed to it.

Let us now examine the reasons for assuming parallelism between internal friction and conductivity. In most cases

the molecular conductivity in aqueous solutions decreases with increase of concentration, and similarly the fluidity. These relations hold, with few exceptions, for aqueous solutions, and it is therefore not remarkable that the fluidity and the molecular conductivity of aqueous solutions should vary at about the same rate. But it does not follow that they are interdependent or to be ascribed to the same cause. If very dilute solutions be employed the fluidity remains nearly constant, but the molecular conductivity of salts increases considerably with dilution, as I have shown in my former work, and my results have been confirmed by Kohlrausch.*

There cannot therefore be a complete parallelism between fluidity and conductivity in aqueous solutions. For very dilute solutions our present views of the nature of electrolysis lead us to conclude that the variation in conductivity is dependent on chemical change, such as the breaking down of complex molecules, the union of molecules of salt with molecules of water, and so on. And the difference between dilute and concentrated solutions is merely a relative one. We cannot draw any definite line between bodies in dilute and in concentrated solution. Thus strong acids in concentrated solution pass through precisely the same phases as weak acids in dilute solution. There is the same relation between alkali salts, on the one hand, and mercury salts on the other. The conclusion follows, therefore, that the molecular conductivity depends chiefly on chemical relations. And there appears no reason to connect internal friction with molecular changes of a chemical nature.

* *Göttinger-Nachrichten*, 25th Feb., 1885,

A similar relation holds between the temperature coefficient for fluidity and the conductivity. These are for dilute solutions approximately comparable, and it might be expected that in extremely dilute solutions they should coincide. I have shown* that such a relation does not hold either for aqueous or alcoholic solutions. Bouty,† who found complete correspondence between these two quantities, was misled by a coincidence in calculating his results, as Kohlrausch has shown.‡

As all known cases can therefore be explained without assuming a connection between internal friction and conductivity, this theory, which serves only to complicate matters, must be for the present abandoned.

As a final proof of the justice of the above conclusion I made a cell like an ordinary Daniell, but introduced gelatine into the solutions of zinc sulphate and copper sulphate. The resistance was 1·5 ohm, while that of a similar Daniell's cell was 1·3 ohm. But the resistance of the cell containing gelatine gradually increased after four days, owing to bubbles being deposited in the gelatine near the zinc and the copper.

CONTEMPORARY PROGRESS.§

ON THE FORM OF THE WAVE SURFACE OF LIGHT IN AN ISOTROPIC MEDIUM IN A UNIFORM MAGNETIC FIELD,

AND

The Probable Existence of a Special Double Refraction in a direction Normal to the Lines of Force.

By A. CORNU, *Comptes Rendus*, Vol. XCIX., Dec., 1884.

AND

An Experimental Verification of Verdet's Law in Directions nearly Normal to the Lines of Magnetic Force.

By A. CORNU and A. POTIER, *Comptes Rendus*, Vol. CII., Feb., 1886.

It is known that a transparent isotropic medium acquires, in a magnetic field, a rotatory power in the direction of the lines of force. Verdet showed by experiment that the rotation of the plane of polarisation is proportional to the intensity M of the magnetic field, and to the cosine of the angle α which the luminous ray makes with the lines of force.

If we write ν' and ν'' for the velocities of propagation of plane waves with circular left-handed and circular right-handed vibrations respectively, Verdet's law interpreted on Fresnel's theory gives to the order of approximation comparable with that of the measurements

$$\nu'' - \nu' = 2k\,\mathrm{M}\cos\alpha$$

whence for light of a given wave-length $2k$ is a constant depending on the isotropic medium.

The author has previously shown experimentally (*C.R.*, Vol. XCII., p. 1368) that the mean velocity of propagation of the opposite circular waves separated by the magnetic action is sensibly equal to their common velocity ν, when there is no magnetic action; so that

$$\nu' + \nu'' = 2\gamma$$

We have, then, assuming the accuracy of the experimental laws,

$$\nu' = \nu - k\,\mathrm{M}\cos\alpha,$$
$$\nu'' = \nu + k\,\mathrm{M}\cos\alpha,$$

Fresnel's geometric method will therefore give the wave surface in the medium when subject to magnetic action.

(Verdet's law alone would not be sufficient, for, though it gives $\nu' + \nu'' = 2u$, it does not require that u should be independent of α, and if it is not, the elimination required to obtain the envelope could not be effected.)

Let each plane wave be referred to rectangular axes with origin O, and with the axis of x parallel to the lines of force of the field. The required wave-surface will be the envelope of

Digitized by Google

a plane whose distance from the origin is equal to the normal velocity of propagation.

The equation of this plane in the usual notation is

$$x \cos \alpha + y \cos \beta + z \cos \gamma = \nu \pm k \mathrm{M} \cos \alpha$$

or $$(x \mp k\mathrm{M}) \cos \alpha + y \cos \beta + z \cos \gamma = \nu \quad . \quad . \quad . \quad (1)$$

with the condition $$\cos^2 \alpha + \cos^2 \beta + \cos^2 \gamma = 0 \quad . \quad . \quad . \quad (2)$$

Differentiating these two equations with respect to $\cos \alpha, \cos \beta$, $\cos \gamma$, as variable parameters and separately equating the coefficients of the independent differentials to zero, we obtain as the equations of the radius vector from the origin to the point of contact

$$\frac{x \mp k\mathrm{M}}{\cos \alpha} = \frac{y}{\cos \beta} = \frac{z}{\cos \gamma} = \frac{1}{\nu} \quad . \quad . \quad . \quad (3)$$

and eliminating $\cos \alpha$, $\cos \beta$, $\cos \gamma$, by means of (2), we get as the equation of the wave-surface

$$(x \mp k\mathrm{M})^2 + y^2 + z^2 = \nu^2 \quad . \quad . \quad . \quad . \quad (4)$$

which consists therefore of two spheres, having the line joining their centres parallel to the lines of magnetic force, one corresponding to the right-handed and the other to the left-handed circular waves.

We therefore have the two following results :—

1. In an isotropic medium in a uniform magnetic field the two sets of waves with opposite circular vibrations (the only waves which can exist), have spherical wave surfaces identical with the spherical wave surface of the medium in its normal condition, with their centres symmetrically displaced along the lines of force.

2. This magnetic displacement is proportional to the intensity of the field, and to the electro-optic constant of the medium.

Special Directions of Circular Magnetic Double Refraction.—If we consider the plane waves propagated perpendicularly to the lines of force, Verdet's law shows that their normal velocities of propagation will be equal, since, under these conditions, there is no rotation. In fact, parallel tangent planes to the two spheres will coincide when they are also parallel to the line of centres, but it also follows that every plane parallel to this line will touch the wave surface in two points, one on the sheet belonging to the right-handed circular vibrations, the other on that belonging to the left-handed vibrations, and the two points will lie in the same plane as the line of centres. Thus the two pencils of light (the *rays* of ordinary double refraction) are separated by an appreciable angle, although the corresponding plane waves coincide ; which leads us to infer the probable existence of a special double refraction in the direction normal to the lines of force—that is, the direction in which it is usually supposed that there is no magnetic action upon light.

The author has hitherto been unable to verify this special double refraction experimentally, owing to its amount being so extremely small. As Verdet's law has only been verified in directions for which the magnetic rotation is considerable, and its exactness has been disputed, MM Cornu and Potier have endeavoured to verify it experimentally for directions nearly normal to the lines of magnetic force. The object which they had in view, in addition to the importance of the law itself, was to show that the two sheets of the magnetic wave-surface cut each other at a finite angle, and that their form is truly spherical. Faraday having discovered that the magnetic rotation ω vanishes in the direction normal to the lines of force, and changes sign when the luminous pencil crosses from one side to the other of this direction, it follows that the angle ω must be an uneven function of the angle β, which the pencil makes with the normal to the lines of force, so that

$$\omega = b\,\beta + c\,\beta^3 + \quad . \quad . \quad . \quad . \quad . \quad . \quad (5).$$

The question to be solved is to determine whether the term in β really exists, the existence of such a term involving, as is easily shown, the consequence that the two sheets must cut at a finite angle proportional to b. If Verdet's law is exact this term must exist, for the law may be expressed in the form

$$\omega = a \cos \left(\frac{\pi}{2} - \beta\right) = a \sin \beta = a \left(\beta - \frac{\beta^3}{6} + \quad . \quad . \quad . \quad . \right) \quad . \quad (6).$$

The coefficient b of (5) must clearly be identical with a of (6), and therefore the result to be sought was a verification of the latter equation. The experimental difficulties were :—

1. To obtain a magnetic field of sufficient intensity to give a measurable rotation in spite of the unfavourable conditions of obliquity. To succeed in this, the tranverse dimensions of the field must clearly be somewhat large in order to increase the rotation by the length of path traversed.

2. To secure that the portion of the magnetic field used for the experiments should be sensibly uniform. The source of electricity used consisted of a Gramme machine and thirty accumulators. The first condition was fulfilled by using elongated electro-magnets with thick pole pieces bent back round the central core, somewhat resembling the hollow electric magnets of Nickles, but differing in the shape of the space containing the wire, which was made in the form which calculation showed would give the maximum external magnetic effect with a given weight of copper wire. Two similar electro-magnets were placed opposite to each other a small distance apart. The free surfaces of the iron cores were about 32cm. in length by 3cm. in depth, and the space between the opposed surfaces formed a field, whose mean intensity reached the value of 6,000 C.-G.-S. units for a distance of 1·3cm. For greater distances the intensity was sensibly in inverse proportion to the distance between the cores.

The intensity was determined by the throw, δ, of a ballistic galvanometer needle due to the maximum induced current produced by a coil having a total surface s (sq. cm.), and turning about an axis perpendicular to the lines of force. The intensity M being given by the formula

$$\mathrm{M} = \delta \frac{\mathrm{E\,C\,R}}{s\,\delta_1} 10^2.$$

The value of the galvanometer throw was determined by observing the throw δ_1, produced by the discharge of a condenser of capacity C microfarads, charged by an E.M.F. of E volts, R being the resistance of the galvanometer.

In the magnetic field, extending horizontally to a length of 32cm., was placed a tube containing a saturated solution of red mercuric iodide and potassic iodide (Thoulet's solution), whose rotatory power is three times as great as that of carbon disulphide. The tube was movable about a vertical axis, and capable of being inclined at an angle of 5° on one side or other of the median line of the field ; with a length of 30cm. with the extreme inclinations the rotation obtained was $\pm 9°$, which could be relied on within 1/200.

The second condition with regard to the uniformity of the field was difficult to fulfil, and, indeed, the results first obtained were only in approximate agreement with Verdet's law. The question then arose whether the want of agreement was to be attributed to inexactness of the physical law or to an insufficient fulfilment of the theoretical conditions.

Clearly, owing to their small thickness, the cores could not give an approximately uniform field, and, though this might have been remedied by using large armatures, it would have resulted in too small a magnetic intensity, the intensity of the field being inversely proportional to the areas of opposed surfaces of the cores. Fortunately, an actual uniformity in the field was not necessary for the experiments, for by Verdet's law the rotation $d\,\omega$ in an element of length $d\,s$ is given by the equation,

$$d\,\omega = \mathrm{A}\,ds\,\mathrm{M} \cos \alpha$$

where A is the electro-optic constant of the medium, and we have $$\mathrm{M}\,ds \cos \alpha = d\,\mathrm{V}$$

where V is the magnetic potential, and therefore

$$\omega = \mathrm{A} \int_{s_0}^{s_1} \mathrm{M} \cos \alpha\, ds = \mathrm{A} \int_{\mathrm{V}_0}^{\mathrm{V}_1} d\,\mathrm{V} = \mathrm{A}\,(\mathrm{V}_1 - \mathrm{V}_0)$$

It was only necessary, then, to show that equal rotations were produced in two columns differing in length, but whose ends were in the same two equipotential surfaces. If in a suitably selected plane, the equipotential lines are rectilinear and parallel, the relation between the lengths $l\,l_1$ of the two columns having their ends on the same two equipotential lines will be

$$l \sin \beta = l_1 \sin \beta_1 \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

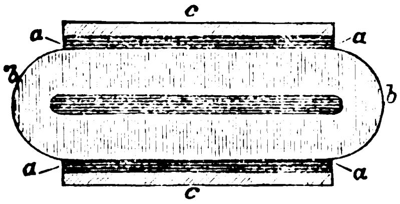
(β and β_1 being the angles made by the two columns respec-

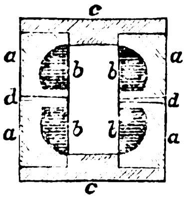
Digitized by Google

tively with the lines of force), the same as if the fields were uniform.

This condition is realised in the horizontal plane of symmetry of the cores when their distance is small compared with their length, as may also be shown experimentally by means of iron filings. The experiments were made by placing in this plane a tube containing the solution and having at its middle point a transverse branch one-tenth of its length, the rotation of a ray traversing the long branch l at different inclinations β to the medium line of the field, and the observations repeated with the short branch l_1 placed parallel to the lines of force ($\beta = 90°$). The experimental verification then reduced itself to showing that the special value of β which gave the same rotation in each of the two branches satisfied equation (3). The results of the experiments agreed well with the calculated values, the error never being more than about 2 per cent., and always showing a slight excess of the calculated over the observed value, indicating that the errors were due to a want of uniformity in the field, and not to inexactness in the law.

Note.—In the *Journal de Physique* for May, 1886 (2nd Series, Vol. V., p. 199), there is a paper by the same authors giving a more detailed account of the experiments, and in this paper the construction of the electro-magnets is described.





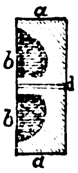


Fig. 1. Fig. 3. Fig. 2.

They are shown in Figures 1 and 2. *a a* are the iron cores, with pole pieces made to surround the coils *l b*, which are kept in position by brass side pieces.

The two electro-magnets were arranged as shown in Fig. 3, being connected by two pieces of soft iron *c c*, an arrangement which was found to increase the intensity of the magnetic field in the ratio of 3 to 5. The blocks *a* were pierced with conical apertures, one in the centre of each block, and the others at distances of 15cm. on either side, to permit the passage of beams of light through the field between the two magnets in a direction parallel to the lines of force.

ON THE ELECTRICAL CONDUCTIVITY OF SOME EASILY FUSIBLE ALLOYS.

By C. L. Weber, *Wied. Ann.* Vol. XXVII., 1886.

The substances treated of in this paper belong to a class showing remarkable variations in molecular structure, *viz.:* fusible alloys of lead, cadmium, bismuth, and tin, and more particularly three special alloys whose variation in volume with the temperature has been made a subject of research within the last few years by Spring, and E. Wiedemann. (Spring, *Bul. Brux.* XXXIX., page 548, 1875, and E. Wiedemann, *Wied. Ann.*, Vol. III., page 327, 1878.)

These are—

Rose's alloy,

48·9 Bi; 23·55 Sn; 27·54 Pb,

Lipowitz's alloy,

49·98 Bi; 12·76 Sn; 26·88 Pb; 10·38 Cd,

and Wood's alloy,

55·74 Bi; 13·73 Sn; 12·73 Pb; 16·80 Cd.

The alloys were melted in an atmosphere of pure hydrogen to avoid oxidation. The measurements of resistance were made with a Thomson bridge, the metal being contained in a U-shaped capillary tube immersed in a glycerine bath.

As the temperature was varied, the changes in resistance took place pretty quickly, and when the temperature ceased to change and was kept stationary the resistance soon assumed its final value.

It was found, however, that the alloys were also subject to a variation of about 3 per cent. of the whole resistance when they were kept for several days at the ordinary temperature. Nevertheless, the general variation of resistance with temperature was found to be the same in each set of experiments.

In the subjoined diagrams the results of the experiments are shown by means of curves, of which the abscissæ represent temperatures and the ordinates represent the specific resistances of the metal, that of mercury being taken as unity.

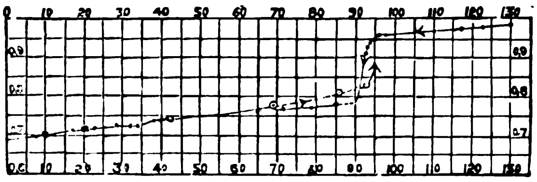

Fig. 1.—Rose's Alloy.

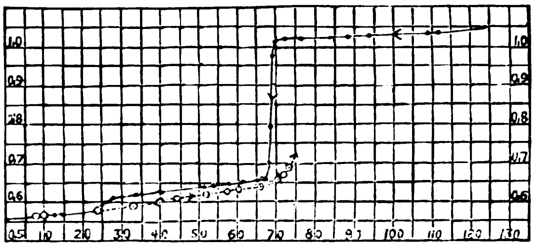

Fig. 2.—Lipowitz's Alloy.

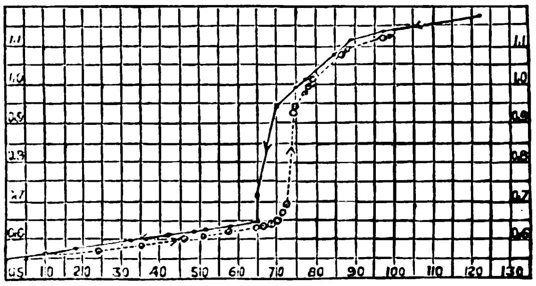

Fig. 3.—Wood's Alloy.

It will be seen from the diagrams that in the liquid state the resistances only vary slightly with the temperature; for example, the temperature coefficient for Rose's alloy in the liquid state is ·0007, and for Lipowitz's it is ·0005.

At the instant of solidification the specific resistances decrease suddenly, as is the case with pure metals, but with the latter this sudden decrease is much greater. When the metal is gradually cooled until it solidifies, the resistance gradually diminishes again, but between 20° and 30° a fresh sudden change takes place, not to the same extent as the first, but very noticeable, nevertheless, in the case of the last two alloys.

If these results be compared with those obtained by Spring for the changes in volume, they are found to differ completely, the curves for the volumes having several maxima and minima, while the changes are most noticeable in the case of Rose's alloy. The two sets of phenomena are not therefore mutually dependent, but they are both due to changes in molecular arrangement. The curves obtained with an increasing temperature are somewhat different from those obtained with a diminishing temperature, being perfectly continuous from 0° to the temperature of fusion, which in this case is higher, as has already been observed by Wiedemann, who considered it to be analagous to the similar phenomenon exhibited by supersaturated solutions.

Wood's metal presents a special peculiarity in the neighbourhood of its melting point, for when slowly cooled down to the temperature of solidification the curve of electrical resistance, previously nearly rectilinear, assumes a more rapid slope, while remaining rectilinear, which is maintained throughout a fall of from 15° to 25° until the solidification point, nearly 70°, is nearly reached, when there is a sudden sharp fall. It would

Digitized by Google

therefore appear that between the liquid and solid states there exists an intermediate state of aggregation, which is stable so long as the temperature is maintained constant, and which is characterised by a special temperature-coefficient.

Wiedemann's explanation of the phenomenon is that at the temperature of 69°, which may generally be taken as the fusing point of Wood's alloy, only a portion of the metal becomes liquid, the rest dissolving little by little, the state of a homogeneous liquid being reached only when the temperature is increased up to 90°.

It appears that this state has no influence on the specific volume, and that the variations in temperature which occur during this time are too small to be shown in the curves of cooling given by Spring.

DYNAMO DESIGN.

In a recent issue of *L'Electricien* M. R. Arnoux has a paper criticising somewhat severely the note recently presented to the *Academie* by M. Marcel Deprez on the magnetic circuit. (An abstract of this note will be found in our issue of November 12th, p. 15.) M. Deprez affirms that "contrary to the views of many electricians, the intensity of the field decreases much less rapidly than the distance of the poles increases." But M. Arnoux points out that according to the figures given by M. Deprez himself, the whole of the experiments upon which this conclusion was based were conducted with exciting powers far beyond the saturation point of the iron. In fact, in well designed machines field-magnets of the same dimensions as those employed in the experiments would be excited with an expenditure of energy not exceeding one-eighteenth of that actually expended by M. Deprez. Under these circumstances, the observations cannot be considered to have any bearing upon the practical questions to which M. Deprez wishes to apply them. In the course of his remarks M. Arnoux mentions that he has himself experimentally established the following theorem :—In a machine of given dimensions, and for a given exciting power, there is always a certain value for the diameter of the inter-polar space, and one only, for which the output of the machine will be a maximum, and one other value, and only one (always less than the former), for which the commercial efficiency will be a maximum.

CLAUSIUS ON ELECTRICITY AND ITS RELATION TO HEAT.

In the German review, *Natur und Leben*, H. Klein, referring to a recent work of Clausius, mentions that the latter strongly insists upon the erroneous character of certain expressions which are in frequent use, especially the phrases "the transformation of heat into electricity," and the converse. Electricity in fact is *not* a form of energy, any more than water or air ; like these, it is merely a vehicle of energy, and cannot itself undergo transformation into either kinetic or potential forms of energy. These ideas are of course perfectly familiar, but it is to be feared that it will be long before practical electricians will see their way to modify their language in accordance with them. Clausius goes on to say that he is gradually becoming more and more convinced that we should cease altogether to talk of "ether," and should deal with radiant heat and light solely in terms of electro-magnetic reaction, and of Maxwell's "electric particles."

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

The following is the continuation of the discussion on Mr. Kapp's paper, "On the Pre-Determination of the Characteristics of Dynamos" :—

Dr. JOHN PERRY said that Mr. Kapp's paper was one which was calculated to do immense good to the members of the Society. The description of the method of calculation was exceedingly easy to follow, even by the most unmathematical manufacturer, and even if exact calculations were not made, the principle underlying the method was the only good guide yet given to the makers of dynamo machines ; it might be said to have revolutionised the construction of such machines. And although Dr. Hopkinson may have used the method first, it had to be remembered that, when Mr. Kapp became convinced of its usefulness, he published it, putting it freely at the service of all engineers. Our gratitude to Mr. Kapp ought to be shown in an unmistakable way. As time was valuable, the speaker would not say what he had come last night prepared to say in support of Mr. Kapp's method of dealing with the magnetic permeability of iron. Immense differences in the law for μ for increasing and diminishing magnetisation produced exceedingly small differences in the characteristic of the dynamo. Prof. Ayrton had mentioned that, with the speaker, he had since last year been experimenting to find out the best practical method of taking advantage of the magnetic and electrical analogy first enunciated by Faraday. They had measured magnetic leakage directly, and also artificially, by reversed currents between conductors immersed in liquids. If the speaker understood Mr. Kapp rightly, he, by guess and trial, determined a leakage resistance, ρ, which would enable him in his calculation to obtain the actually observed characteristic of a dynamo. He could then assume that in any similar dynamo ρ was inversely proportional to the dimensions of the machine. Dr. Hopkinson took quite a different method, and he ventured to think not so correct a method as Mr. Kapp's. He assumed a leakage, which was a constant fraction of the useful induction. He measured this directly on the machine by coils of wire and ballistic galvanometer. Neither Mr. Kapp's nor Dr. Hopkinson's method could, therefore, be applicable to a new kind of machine before the machine was constructed. It was this defect in the method, this necessity for a determination of the probable leakage, which caused the speaker to listen so intently to Prof. Forbes ; for Prof. Forbes attacked this very question. He could not say, however, that he thought Prof. Forbes's method of calculation very valuable. Prof. Forbes said that he did not have to use his judgment in making the calculation, but the speaker thought he had exercised his judgment very liberally. He settled beforehand from what places leakage took place, he settled the shape of its paths, he restricted its paths to very confined portions of space. The only fact which was mathematically certain about such a calculation was that its result must be less than the real leakage. Why did Prof. Forbes neglect utterly the leakage from the faces of the magnet limbs remote from one another ? He left out all sorts of possible leakage. To make up for this he took the leakage from limb to limb as if every point of each were at the same potential—namely, the mean potential of each, and hence his result ought to be half as much again. The speaker had no faith in the value of such a method of calculation. Prof. Forbes had a right to feel proud, not of the value of his method, but of his great good fortune in obtaining an answer which fairly well agreed with the experimental result ; every user of the method might not have the same good fortune. He understood that Dr. Hopkinson objected to the use of the analogy between magnetic induction and the electric current. Presumably this objection was not to the analogy in its essence ; but since the magnetic resistance of iron varies with the amount of induction, it is probably thought that the use of the analogy might cause this fact to be kept out of sight. But in the particular case of the field-magnets of a dynamo the speaker had gone carefully into the question, and found, assuming some such law for μ as Mr. Kapp has taken, we may, until four-fifths of the saturation induction have been reached, really regard the leakage resistance as a constant for all magnetisation. This is a point of very great importance. Mr. Kapp assumes the constancy of ρ, but Dr. Hopkinson, knowing that there cannot be an absolutely constant leakage resistance, has not seen that it may practically be regarded as constant, and he has made an assumption which is not by any means so defensible. The speaker concluded by advocating the use of a simple empirical formula like that of Frölich, which he claimed to have used for dynamos with Prof. Ayrton for some years before Frölich published it.

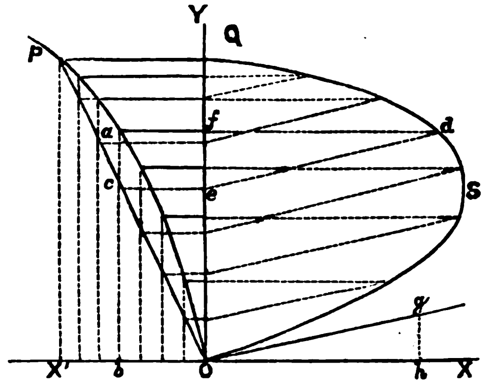
Mr. KAPP was then called upon to reply upon the whole discussion, and said that, before referring in detail to the various questions which had been raised during the discussion, he would like to say a few words upon a point which, he feared, had not been made sufficiently clear in the paper itself. This was the question of the relative importance of the waste field at different degrees of magnetisation. Some of the speakers appeared to be under the impression that he had denied the existence of leakage in a weak field ; but this was not his intention. What he had said was that since at low degrees of magnetisation the resistance of the armature and magnet was very little greater than its initial value, and was also very small in comparison with that of the air space, the leakage had very little influence upon the exciting power. Mr. Kapp then pointed out that in the electrical analogy this was equivalent to the case of a battery of low internal resistance doing work in a circuit. The addition of a shunt of high resistance (corresponding to the magnetic leak) would not, then, sensibly diminish the E.M.F. at the terminals of the working circuit. On the other hand, if the internal resistance of the battery be increased

Digitized by Google

while the total E.M.F. and the resistance of the shunt be kept constant, then the influence of the shunt in reducing the E.M.F. at the terminals will become more and more apparent. This is analogous to the case in which, while the leakage resistance remains the same, the magnetisation is increased, and with it the magnetic resistance of the iron. Thus, at low degrees of magnetisation, leakage has no sensible influence, but it has an influence at higher degrees. But even at higher degrees its detrimental effect is not so great as some of the speakers appeared to imagine. He was glad that Prof. Ayrton's experiments confirmed his own views with regard to parallel resistances. (Prof. Ayrton here expressed some dissent from this statement, but Mr. Kapp pointed out that the discrepancy between his own formulæ and those of Prof. Ayrton was only apparent, the four equations contained in his own paper reducing to the simple expression for the law of parallel circuits as preferred by the Professor.) Mr. Swinburne and Mr. Esson had raised the question as to the best relative proportions between the sectional area of the iron in the field and in the armature. Mr. Esson had given some figures taken from actual practice. Unfortunately, however, he had reason to believe that in several cases these referred to machines now obsolete. As a matter of fact, no hard and fast rule could be given, as the ratio must largely depend upon the particular purpose for which the machine was to be constructed. He thought, however, that in arriving at the ratio 3 to 4, Mr Esson had reduced the relative proportion of iron in the field to as low a point as could ever be really advantageous. Mr. Fricker considered it more correct to describe exciting power in terms of ampere feet, but on taking into consideration the *area* enclosed by a coil, it would be found by an elementary investigation that this came to exactly the same thing as ampere turns. The latter form was, however, more customary and more convenient. Mr Crompton had said some very encouraging things for the benefit of our mathematicians, but he had at the same time thrown cold water upon those who were not gifted with that peculiar "eye" for details of this nature. Mr Kapp then pointed out that, so far as he was concerned, the establishment of the fact of the desirability of increasing the sectional area of the iron of the magnets dated from his discovery of a certain empirical formula for the E.M.F in a Bürgin machine, which, although now known to be incorrect, yet distinctly indicated the necessity for an increase in the quantity of iron. It was true that the final conversion was effected by the aid of a machine which Mr. Crompton had built, but which at the time he (Mr. Kapp) had characterised as containing a "ridiculous" quantity of iron. But it was also true that the same machine effected Mr. Crompton's re-conversion a certain distance in the opposite direction (laughter). If it be permissible for the author of a paper to offer his congratulations to a member who has taken part in the discussion, he should like to do so in the warmest possible manner to Prof. Forbes, whose laborious and painstaking investigation of the leakage in every part of the magnetic circuit of the machine, dealt with by Dr. Hopkinson, excited his greatest admiration. In common with Prof. Perry he could not, however, avoid feeling some misgiving as to the general applicability of the method. The design for a dynamo without leakage, which had been given by Prof. Forbes, would only partially fulfil this purpose; but, on the other hand, it had a decided advantage, which he did not name, in that it saved one half of the wire on the field. Mr. Kapp then showed his design of a four-pole dynamo to effect the same purpose, and which he published about a year and a half ago in *The Electrician*. He had himself never made a machine of that construction, but he noted that a four-pole machine, of almost identical construction, was now being made, under the name of the "ironclad dynamo," by Mr. Kennedy, of Glasgow. Mr. Elwell had also, only a few hours ago, told him that he had made one of these four-pole machines quite recently, and found it very efficient, and cheap to manufacture. Dr. Hopkinson had told them something about the methods of measuring the minimum induction obtained. Upon double horse-shoe machines this measurement might be still more easily carried out in the following way:—Remove the armature and couple the four exciting coils so as to magnetise the field-magnets in a continuous direction. This will produce great crowding of the lines of force through the middle portion of the pole-pieces where the latter have least thickness. In these portions we shall therefore have saturation, and the total induction can be measured by a turn of wire round that part and a ballistic galvanometer in the usual way. Mr. Walker and other speakers had assumed that a leakage of 25 per cent. in the total number of lines meant a waste of 25 per cent. of the existing power. This, however, was not the case, for if the narrowest section of the field was increased by 25 per cent. in width, the perimeter, and, therefore, the length of the exciting coils, would under practical conditions receive a very much smaller increase, amounting in a case assumed in illustration to only 7 per cent. Prof. Silvanus Thompson complained that the true characteristic had not been given, but only the characteristics of magnetism But the problem of deducing the one curve from the other is merely a geometrical exercise, with which he did not think it desirable to occupy the time of the society. Prof. Thompson also objected to the selection of a particular point in testing the Frölich formula, but to adopt his own suggestion would have required the verification of the formula at the same point upon the curve as that selected at first. If Frölich's curve will not stand any harder test than this, we had better call it in future Frölich's point. Prof. Perry also vindicated the employment of Frölich's formula, and he was perfectly willing to admit its utility, provided always that the leakage be taken into account, which was, however, not done either by Frölich nor by Thompson. Mr. Kapp concluded his remarks in the following terms:—Now about my unfortunate units. I need hardly say that last week my heart sank within me when one speaker after another took me to task in the most severe fashion for having employed some special units. Prof. Thompson said that my system is a mixture of C.-G.-S. and inches and minutes. I beg to say that my system is no mixture, and that it contains not a single shred of the C.-G.-S. A man totally unacquainted with grammes and centimetres can use my formulæ, and will know what he is doing. Can the same be said about the C.-G.-S.? Only last week one speaker called that a gauss, which another called a milligauss, the ratio being nothing less than one to a million. Is that not a little mixed? It is significant that practical dynamo makers have not as yet raised any objection to my system. I know that Mr. Fricker, for instance, uses it and makes very good dynamos. He could use the C.-G.-S. equally well (for the translation of one system into the other is really a very easy matter), but he is content with my formulæ as they are given. The difficulty in adopting C.-G.-S. in actual work is that we cannot talk to our workmen of centimetres and grammes. We must conform to usual practice and to English measure, and therefore it saves labour to make the calculations in a system where the figures are of reasonable magnitude and are directly applicable for purposes of the workshop.

DYNAMO CHARACTERISTICS.

The following is the solution of the problem of determining graphically the external characteristic of a shunt-wound dynamo from the curve of magnetisation of its field, as given by Prof. Silvanus Thompson during the recent discussion on Mr. Kapp's paper at the Society of Telegraph-Engineers:—



Let $O a P$ be the curve of magnetisation, which for this purpose is drawn on the reverse side of the axis O Y, and let $\tan C O b$ be the resistance of the field-magnets, the current in these coils being taken along O X'. Let $\tan g O h$ be the resistance of the armature, and let the total current be taken along O X. Then each point on the external characteristic O S Q is determined by the following construction: At any point a on the curve O P let fall a perpendicular $O b$ to the axis O X'. From the point a also draw a line parallel to O X', cutting the axis O Y, and produced indefinitely upon the other side. From the point c, where $a b$ cuts the tangent line, draw $c e$ parallel to O X, and from the point e on the axis O Y draw a line parallel to the tangent line $O g$, cutting $a f$ produced at the point d. Then d is a point on the required curve. By a similar construction at as many points on O P as may be necessary the curve O S Q may be traced out.

The proof is, of course, very simple. Let E be the total internal E M.F., C the total current*, C_1 the shunt current, R_1 the resistance of the shunt, and r that of the armature, then

$$C = \frac{E - C_1 R_1}{r}$$

$$= \frac{a b - O b \,.\, \tan c O b}{\tan g O h} = \frac{a c}{\tan g O h},$$

* From the form of the diagram given by the Professor it is evident that he has obtained the characteristic for the *total* currents, instead of, as is more usual, for the current in the external circuit only. A very simple and obvious change in the construction would give the true external characteristic.

Digitized by Google

which by construction $= \frac{fe}{\tan f d e} = fd.$

Therefore d is the point on the characteristic curve corresponding to the point a taken on the curve of magnetisation.

GLOW LAMPS, THEIR USE AND MANUFACTURE.*

BY MAJOR-GENERAL C. E. WEBBER, R.E., C.B.

It is not my intention to enter into any dissertation on the various kinds of glow or incandescent lamps which have appeared from time to time since their first use by De Moleyns, Starr, and King, between 1840 and 1850, nor do I wish to trouble my audience with the history of inventions which have led up to the so-called glow-lamp now in commercial use. The word "incandescent" or "incandescence" lamp is, like all other adjectives of four syllables, cumbersome, and the word "glow" has been adopted by many, and is for our purposes sufficiently expressive to identify a means of domestic illumination now almost as familiar to the public eye as the gas jet. From the point of view whence I beg my audience will regard the subject, it is my desire to lead them to realise that in the manufacture of glow lamps we have a rapidly growing industry, in the increase and efficiency of which they may all before long be interested. And I shall only remind them of the antagonisms of rival inventors and the struggles for precedence arising out of the same when that part of the question is necessary to my subject. It is true that the time has not yet arrived when a general audience can be expected to evince as much interest in my subject as they would naturally do in the lectures on candles or lamps delivered in this hall, but it is believed that a more general knowledge of this very interesting subject will aid in its popularisation, and will bring home to many who have not yet accepted the fact, that illumination by electricity for home purposes is a reality, and that this little bulb, containing a filament which becomes incandescent by the passage of a current of electricity, has made possible and practical a system of illumination which we who use it would gladly convince everyone is superior from a sanitary and economical point of view to any other known means. A great deal too much that is unreasoning has been said here and elsewhere as to these advantages. Allow me for a short space to draw attention to some points connected therewith. When the glow lamp was first introduced, its promoters misled the public judgment and eye by claiming for it more duty than it was able to perform. It was shown in exhibitions, where each exhibitor vied with each other in one direction, namely, in creating a blaze of light, where the little glow lamp was placed alongside the powerful and intense brilliancy of the arc electric light. The exhibition of lamps of 16 to 20 candle-power in groups became the custom, and the public was unconsciously led to compare these, in their minds, with gas jets and Argand burners of far lower real candle-power. When they went further in their inquiries with the view to practical adoption, they were immediately met by the inequality of cost, which although in the first instance is due to the outlay in plant for supplying electricity, is heavily weighted with a factor arising out of this want of consideration of the relative candle-power of the lamps and other means of lighting. Born and educated in the use of illuminants which present to the eye a soft wide gaseous flame, having a measurable iridescent surface containing incandescent particles widely dispersed, we were quite unprepared to estimate the increased power of the brilliant little line of intense incandescence that meets our view when we regard this glow lamp. Those with eyes able to bear its penetrating effects hailed it as a means of increasing light, regardless of the extravagance in using more than they actually required; and those with sensitive retina submitted to it as preferable to the overpowering glare of the arc.

From its use in exhibitions, and with the traditions of the gasfitter, electric light crept into our places of public resort, and thence into our dwelling rooms. Wherever one went, either the gasfittings were made the supports of the glow lamp, or it was hung from the ceiling, so that on entering a room lighted by a number of these pendants a brilliant line of light cut the eyes like the blow of a whip lash, rendering everything for a time obscure. Indeed, from careful study of places lighted with the glow lamp, I have come to the conclusion that the eye is much longer recovering the effects of this sudden slight paralysis of its light receptive powers than is supposed; and that this cry of more light which one hears, where the subject has been dealt with from a gasfitter's point of view, is simply due to temporary observation and loss of power to discover the true needs for illumination of the surrounding objects. In more than one club in London, where the lines I have referred to have been followed in applying electric light, although the candle-power of the latter is about three times the value of that of the lamps previously in use, there is a constant outcry from the young eyes that "there is not enough light," and from the old eyes that "they know not where to go to avoid the glare." Of the remedies suggested for this, I cannot subscribe to one which has emanated from a well-known architect which has come to my notice, namely, that as the position of the sun, our illuminant by day, is overhead and high up, out of the ordinary direction of vision, so we ought to make use of electric lights by placing them high up in our rooms, and increase their power and number, in order to make up for the loss of light due to distance. Hence the introduction of glow lamps into the ornaments of the frieze at a well-known restaurant, and their substitution for gas jets, lamps, and candles in chandeliers and sunlights. When regarding this question from the point of view of economy, we see the reason why the cost of electric lighting has so much deterred its use in competition with cheap gas; at the same time the still cheaper arc electric light is ignored or condemned. The screening of glow lamps from direct vision adds still further to the cost of lighting, but if arc lamps were more used their cheapness would allow of much light being wasted in concealing their brilliancy by deriving the light only from reflecting surfaces. The efficiency of arc lamps is now so well secured that the old objections to them should fast disappear. That concerning the so-called ghostliness of the light has been completely dispelled by the experiments of Captain Abney and others on the subject of the colour of the electric light.

The conclusions I have come to, after visiting electric light installations at home and in many parts of the Continent, are that with all kinds of electric lamps used in interiors, the eye ought never to be allowed to meet the source of light, even when subdued 30 per cent. by transmission through obscuring media; that arc lamps should be employed in all large spaces, placed well overhead, and as much as possible so that their rays shall meet the eye of the uplooker by reflection only; that glow lamps should be invariably shaded from the eye, and so placed as to be as near as possible to the object to be seen—for instance, on brackets attached to the frames of pictures with opaque reflectors; for dining tables with white table cloths, well concealed in nearly opaque shades. For reading or writing, small candle-power lamps are ample, and least injurious to the eye if concealed in opaque shades suspended from curved table stands about twelve inches from the paper. For general illumination of rooms the shades may be more or less semi-opaque, but the reflectors or diffusers should be as brilliant as possible. Lately, the Council of the Royal Albert Hall has been making a few experiments in the distribution of light within that noble building. Both arc and glow lamps have been tried; the former in the upper, the latter in the lower part of the hall. With the arcs it was found that only in the upper arcade could they be concealed from the eyes of the audience. The effect of brilliantly lighting it up with twelve 2,000 candle-power arcs was good; but the light reflected into the body of the hall by the back wall was probably only one-tenth of that yielded. Six more such lamps placed high up in the lantern were of no more use than moonlight would have been; but when lowered below the level of the cornice gave directly or by reflection their full effect. When all the eighteen were suspended in a group and let well down into the body of the hall, the illuminating effect on objects was inferior to that of the thirty-two gas pendants, each with sixty gas jets, which are suspended all round the hall just above the arcade; but when one turned the back to the light the same print was equally easily deciphered.

What the effect of diffusing the light of such a group would have been if the lamps had been confined in an obscured glass lantern remains to be proved. Advocates of concentration and of dispersion of the arc lamps were found; but when it came to the concentration or dispersion of the glow lamps used in the trial, there was little difference of opinion as to the good effect of throwing the light from them towards the backs of the boxes, by placing them under the ceilings of each box, and concealing them from the eye of the audience. Some will recall the gloomy cavernous effect of the three tiers of boxes at the Royal Albert Hall; lighted up, as some of them were for the trial I am describing, the scene was pronounced fairy-like. The lights were placed so as to be of no inconvenience to the occupants; but the effect was to lighten the whole aspect of the elevation, and as every lamp was concealed, the eye could dwell on features of construction and colour which before were no more than masses of shade. This concealment of the glow lamps was also carried out on the orchestra stage under the organ, where the trial was equally successful in demonstrating the fact that, although the loss of light may be considerable, by following such a course that loss is a gain when it can be proved (of which there is no doubt) that the eye is far better able to examine the objects around the concealed lights than if they were exposed. It is curious how in theatres this theory of the advantage of concealment of light is carried out on one side of the house and not on another. At Buda Pesth I saw this well exemplified, where a large theatre was being lately lighted by electricity. Above the stage, and concealed among the suspended scenery, were seven treble rows of twenty glow lamps, arranged so as to be altered, raised, and lowered in various ways, but, alike with the footlights, not one could be seen by the audience; whilst in the auditorium itself the gasfitter again resumed his sway, and between chandeliers and brackets on the fronts of the boxes and galleries, the lights were successfully placed so that the dazzled eye could not dwell for a moment on the beauties, either physical or decorative, of a very beautiful building, crowded with an audience which came as much to be seen as to see. A very simple example will enable you to realise what most who have thought of these matters well understand, namely, the entirely different conditions which are being dealt with in using candles, lamps, or electric glow lamps. Photometrically each of these yield light of the value of about ten candles; but how different is the impression on the eye. Does it not show that these must be dealt with and employed differently in their use for illuminating our hours of darkness and to meet our various wants. Because artists love and seize on the effects of highly contrasting light and shade to perpetuate striking scenes, there is no reason why we should live under such conditions. Though a beautifully dressed woman may appear to great advantage for a minute under a brilliant flood of light, she would, I think, sacrifice the full effect of her splendour rather than always remain long under its influence.

One might go on for ever with examples of this kind. The real cause of so much difference of opinion on the question probably lies in the varying conditions of the human eye, in respect to its sensitiveness of light, and its power to recoil from its effects before temporary injury has been done to it.

From the manufacturing point of view, the glow lamp consists of three distinct parts, namely:—The filament, the wire mount or conductor, the glass bulb. The amount of research and experiment which has led to the perfection which now we may safely say exists in these three has been very large. It would be invidious to particularise individual labours, and the list would be too long to occupy the time of the present occasion. The burner, or bridge, has been the subject of a large part of these labours.

* Paper read before the Society of Arts, Wednesday, December 8, 1886.

Digitized by Google

The conditions which it should fulfil are various, and a good filament for the purpose has been produced from various materials. But the object of most inventors has been to find a highly refractory substance, and they have all ended in using carbon of either a fibrous or amorphous consistency, which they produce in the shape and of the nature which they require, by various processes. The conditions of form, density, uniformity of section, surface and electrical resistance, with which a glow lamp bridge must be endowed are now well understood. First, the form has been governed by the need to hold within a bulb of a given size a carbon wire of a given length. The simplest example of the means resorted to to achieve this is shown in this lamp, in which it will be seen that by giving the filament a coil, one of about seven inches in length is contained in a bulb only three inches in length, without unduly approaching the glass. Another condition of form is that of uniformity of section. With some of the raw materials used, it is almost impossible to obtain this in the early preparation without gauging them in a die, by means of which the irregularities of surface are scraped off before the thread or strip is bent into form previous to baking. This is the case with the material of the Edison filament, of the preparations of which, from especially selected bamboo in all its stages, we have seen beautiful examples at the Paris and Crystal Palace Electric Exhibitions. It is not the case with the filaments prepared by squirting a viscous solution of cellulose into a precipitating solution, a process which produces at once the most perfect uniformity of section, such as that used for making the filaments, for instance, of the Victoria Brush glow lamp. It will be at once understood that the after stage of deposing carbon by the process discovered by Marcel Deprez is not essential to the obtaining of such uniformity in the latter case as it is in that of other inventors, who carve it out of raw vegetable material of either a fibrous nature, or out of strips of paper or parchment. Most of these raw materials are by way of being trade secrets ; indeed, in the case of one glow lamp maker on the Continent, I know that the inventor has never divulged his secret, and that he prepares the raw material in the privacy of home, and brings it to the works in such a form as almost to defy detection of its origin.

The raw material is generally wound on to blocks of carbon, and then baked at high temperatures. Here, again, we have a stage in the preparation of filaments which has given rise to a great deal of labour and research. The reasons for the varying results obtained from bakings were at first very obscure. With some kind of materials, filaments off the same blocks, and off different blocks, showed differences of contraction, causing fracture in the process, differences of tensile strength, and of surface, for which it was difficult to account.

Various means were adopted to regulate the rate of increase and decrease of the temperature in the oven, to exclude oxygen from contact with the baking, and the results as often misled the engineer as they helped to bring him to the desired standard process. All who have been through this will bear witness to how often they were disappointed, and how only by slow, steady, and patient investigations and collaborations of results they at length were able to deduce the conclusions which have led them to the true path which must be followed in the preparation and process of baking the raw material, from which they have seen no reason since to depart. To produce a carbon more or less dense and uniform has been the object of all, but if I have been understood, it is obvious that I attach the most importance to that process by which sufficient density and uniformity of section and surface are actually reached at this stage of the preparations of the filament.

We now have to study a stage which may be regarded as the most important with reference to the commercial use of the glow lamp. So early as 1878 it was discovered, or revealed, that in order to be able to use a large number of glow lamps on one system they must all be subject to the same electrical conditions of tension. It was found that it would be impossible to maintain uniform illumination in all the glow lamps on a system if each lamp was to be subject to different conditions of pressure ; and that the only way to achieve a practical result was to connect one terminal of all the lamps to a main conductor conveying a current in the first place sufficient for all the lamps destined to be used in the system, and in the second place having an E.M.F. or potential above zero (zero being an empirical "earth"), of an energy suitable to bring the filament to a state of incandescence ; and so arrange that the value of the E.M.F. should be the same throughout.

In other words, the system of distribution known as the parallel system was thus practically discovered. The second or return conducting path is, of course, necessary when dealing with a physical development of energy such as what we call "electricity," to complete the circuit to the so-called negative terminal of the dynamo, or other source.

It will readily be appreciated that the word "parallel" is a misnomer, the parallelism of the conductors having nothing to do with efficiency ; and that their being carried alongside of one another throughout a building only arises out of a desire to economise the labour of the workmen who have to put them up.

It would, I conceive, be well if the public, and above all the insurance companies (for it is largely a question of fire risk), could be brought to understand that the second or return wire is electrically the same as the "earth" of the electrician, and that so long as the positive, or supply wire, is well insulated and kept far apart from the negative, or return wire, no further precautions are necessary ; and when they are thus far apart, even if one is bare, greater security is obtained than by the present system, which unreasonably insulates the wire which need not be in a state of electrical tension, as well as that which is always ready to discharge. I have digressed a little way to show why absolute uniformity in the glow lamps is necessary to such a system ; nothing in its condition could be made to compensate for any defect in that respect. The chief aim, then, must be to secure this uniformity in the manufacture of the filaments of glow lamps.

(To be continued.)

THE INSTITUTION OF CIVIL ENGINEERS.

At the ordinary meeting on Tuesday, the 7th of December, Mr. Edward Woods, President, in the chair, the paper read was on "The Electric Lighthouses of Macquarie and of Tino," by Dr. JOHN HOPKINSON, F.R.S., M. Inst. C.E.

The author stated that the subject of the use of the electric light in lighthouses had been fully discussed at the Institution in 1879, when papers by Sir James Douglass, M. Inst. C.E., and by Mr. James T. Chance, Assoc. Inst. C.E., were read. The subject had been further elaborately examined by Mr. Allard, and more recently in practical experiments, made at the South Foreland, which had been exhaustively reported on by a committee of the Trinity House. The justification of the present communication was that, at the lighthouses of Macquarie and of Tino, the optical apparatus was on a larger scale than has hitherto been used for the electric arc in lighthouses, and presented certain novel features in the details of construction. In the case of both lighthouses, Messrs. Chance Brothers and Co., of Birmingham, entered into a contract for the supply of all the apparatus required, including engines, machines, conductors, lamps, optical apparatus, and lanterns. In both cases Sir James Douglass, engineer-in-chief of the Trinity House, acted as inspecting engineer to the respective Colonial and Foreign Governments.

At Macquarie there was a revolving light, giving a single flash of eight seconds' duration every minute. Owing to the altitude of the lighthouse (the focal plane being 346ft. above the sea) it was necessary to secure that a substantial quantity of light should be directed to the nearer sea ; but it was also essential that this dipping light should be but a small fraction of that sent to the horizon, otherwise its effect would be excessively dazzling. The optical apparatus was of the first order, 920 millimetre focal length, and the condensing effect was produced by a single agent ; that was, vertical straight prisms were dispensed with. Forms not differing very greatly from those introduced by Fresnel had been adopted, and were specially arranged for the purpose in hand. The upper and the lower totally reflecting prisms were forms of revolutions about a horizontal axis ; they directed the light incident upon them to the horizon and the distant sea, from 10′ above the horizon to 30′ below ; they were adjusted to distribute the light in azimuth over the arc of 3° necessary for a proper duration of flash. The refracting portion of the apparatus had the profile so calculated, that the central lens, and the three rings next to the lens above and below, directed their light to the horizon without vertical divergence, except what was due to the size of the arc ; the light for the nearer sea was obtained from the remaining ten lens-segments. From half a mile to three-quarters of a mile the sea received light from one element of the apparatus, from three-quarters to one and a quarter mile from two elements, from one and a quarter mile to two miles from three elements, from two to two and a half miles from four elements, beyond two and a half miles from six elements ; the upper and lower totally reflecting prisms came in aid at about five miles. The main power of the apparatus was hardly attained till a distance of eight or ten miles. A dioptric mirror was placed on the landward side of the arc. This mirror was arranged to form the image of the arc at one side of the carbons, so avoiding the interception of light which would result if the mirror were used in the ordinary way. Further horizontal divergence was given by the form of the lens. In the ordinary revolving light the inner face of the lens was plane, here it was cylindrical, the axis of the cylinder being vertical. The lamps were of the Serrin type, and were supplied by Baron de Meritens, who also provided two alternate-current dynamo machines, with permanent magnets. Each machine had five rings in its armature, and in each ring there were sixteen segments. In supplying one arc for a lighthouse the machine ran about 830 revolutions per minute, and gave a current of 55 amperes when half the coils were used, and of 110 amperes when the whole of the machine was in action, the internal resistance in the two cases being 0·062 and 0·031 ohm. Each machine was driven by an 8 horse-power Crossley gas engine, through a belt without counter shafting. Whilst the dynamo machines were at the works of Messrs. Chance Brothers and Co. a series of experiments had been made in March, 1881, to determine their properties. When the external resistance was a metallic conductor of small self-induction, it was found that with varying resistance and speed the currents observed agreed fairly well with calculation from the formula $\frac{A}{\sqrt{R^2+\left(\frac{2\pi\gamma}{T}\right)^2}}$ in which R was the total resistance of the circuit, γ the self-induction, and T the periodic time. When the machine was running 830 revolutions per minute $A=67$ volts and $\left(\frac{2\pi\gamma}{T}\right)^2=0{\cdot}197$ in ohms squared, hence $\gamma=6{\cdot}4\times10^5$ centimetres. The eighty sections of the machine were arranged four in series, twenty parallel. For a single section the value of γ would be 32×10^5 centimetres. The maximum induction in the core, which had an area of 5 square centimetres, was 24,600, or 4,920 per square centimetre. The loss of power was greater when the machine was doing little or no external work than when that work was great. This was clearly seen from the following table :—

Current amperes	7·70	73·60
Electrical work horse-power	0·69	5·66
Mechanical work applied	3·09	6·55
Loss	2·40	0·89

The explanation had been pointed out in the lecture by the author on "Some Points in Electric Lighting." Photometric experiments were made upon the arc, and simultaneous measurements of effective power applied and of current passing. The red light was measured through a bright copper ruby glass, and the blue through a solution of sulphate of copper and ammonia. The horse-power was measured by a transmission dynamo-

Digitized by Google

meter; but the results must be accepted with some reserve, on account of the difficulty of ascertaining the mean tension in a strap which was constantly varying. The oscillations of the dynamometer were damped by a dash pot containing tar.

	Half Power.	Full Power.
Red candles	1,988	4,708
Blue ,,	4,079	11,382
Current (amperes)	54·5	105
Mechanical power applied (H.-P.)	4·5	6·9
Power expended in heating conducting wires (H.-P.)	0·24	0·95

The results illustrated the fact that, as the current increased, the total light increased in a higher ratio, red light in a slightly higher ratio, and blue in a ratio considerably higher. The machinery for this lighthouse was sent out to New South Wales in November, 1881. The glare of the light upon the sky was said to have been seen at a distance of over sixty miles, far beyond the distance at which it would cease to be directly visible.

The distinctive character of the Tino light was a triple flash every half minute. The apparatus for producing this effect was of the general form introduced by the author in 1874. The second order apparatus of 700 millimetre focus was adopted in this case. The horizontal divergence was obtained in exactly the same way as at Macquarie, excepting that no mirror was used. The quantity of light thrown upon the nearer sea was very much less in the case of Tino than in that of Macquarie, and greater reliance was placed upon the accuracy with which the arc could be kept in focus; experience had justified these changes as improvements of a perfectly safe nature. As there was no water upon the island, two Brown hot-air engines were supplied, each driving through a countershaft one of the machines. The countershafts could be connected by a Mather and Platt friction-coupling, so that the two machines could be driven together, or either machine from either engine. In future lighthouses, when a steam engine could not be employed, it would be preferable on every ground to use gas engines, and to manufacture on the spot either Dowson gas or ordinary gas, according to the character of the fuel available. There were two dynamo machines of exactly the same type as those supplied for Macquarie, the only novelty being in the method of using them. One of the three lamps was of larger size, for the double-power current of 200 amperes from the two machines when coupled together. This lamp was said to be suitable for a still greater current, but with about 200 amperes it soon became dangerously heated; a simple modification rendered the lamp equal to the actual work it had to do. The apparatus was delivered in November, 1884, and was put up by workmen from Messrs. Chance's workshops, under the supervision of Signor L. Luiggi, of Rome. A complete test of the performance of the light, as seen from the sea in all grades of its power, was made in April, 1885, by a commission appointed by the Italian Government. The light was well observed through rain when distant 32 nautical miles, and although below the horizon the position was precisely localised, and the triple-flash distinction unmistakable. At 18 miles distant the illumination of the flash upon white paper was sufficient to make out letters marked in pencil 1¼in. high, and when 14 miles distant it was easy to ascertain the time from a watch. The light was frequently seen at a distance of 50 miles, near to Genoa.

Some general points were dealt with at the end of the paper, and particulars were given of a plan for providing an electric lighthouse at about the same cost as a first-class oil lighthouse.

LEGAL INTELLIGENCE.

Eck, Callow and Co. v. Heath.

This was an action heard before Mr. Justice Kekewich on Friday last, in which the plaintiffs, a firm of electrical engineers and instrument-case makers, carrying on business at 11, Greville-street, Holborn, asked for a declaration of the Court that the agreement which they entered into with the defendant for a lease of the aforesaid premises for 21 years should be rescinded, on the ground of misrepresentation and concealment on the part of the defendant at the time the agreement was entered into of certain facts, which subsequently brought them into expensive litigation, and prevented them from carrying on their business.

Mr. Barber, Q.C., and Mr. Oswald appeared for the plaintiffs, the defendant being represented by Mr. Warrington, Q.C.

Mr. Barber said that the plaintiffs entered into an agreement on the 10th of April, 1885, with the defendant for a lease of the said premises for a term of 21 years, at a rental of £70, and a further sum of £50 for the use of a steam engine which was at the time on the premises. But the plaintiffs had not been long in possession when a Mr. Gardiner complained of the noise of the machinery, and on the 13th of May commenced an action against Messrs. Eck, Callow and Company. The Court on that occasion ordered that the matter in dispute should be referred to an arbitrator, and, accordingly, it was referred to a Mr. Archibald, an engineer of considerable experience. On the 4th of August of the same year the arbitrator furnished a report embodying his views as to the substance of the action, the result of which was that the plaintiffs were restrained from continuing any longer driving their engine and pumping apparatus which caused the nuisance complained of by Mr. Gardiner. The plaintiffs, when they entered into the agreement, were assured by the defendant Heath that the noise of the machinery would not be objected to by the neighbours—that, in fact, he (the defendant) had obtained the sanction of the neighbours to work it. Hence the present action, in which the plaintiffs also sought to recover damages for the loss they had sustained in consequence of the litigation which had been forced upon them.

Mr. Douglas James Callow was called and examined and cross-examined by Mr. Baker and Mr. Warrington upon the negotiations he had with the defendant before entering into the agreement, his answers substantially endorsing the foregoing statement. In the end, by the advice of the Judge, who remarked that it was one of those cases which ought never to have been brought into court, it was agreed between the parties to settle the matter amicably, each side paying its own costs, and the plaintiffs obtaining the relief they asked.

NEW COMPANY.

The Manchester Electric Supply Company (Limited) has been registered by G. Maclaren, 22, Chancery-lane, on the 3rd inst. The objects are said to be to light streets, public places, mines, ships, railways, tramways, or any other places or things by means of electricity, or other similar agency. To create or produce electricity, or other similar agency, and to supply the same for the production or transmission of power, for lighting purposes, or otherwise. According to the Memorandum of Association, the usual powers are taken as to leases and purchase. The capital of the company is £10,000, divided into 1,000 shares of £10 each.

The first subscribers are—	Share.
J. T. Chancellor, C.E., 31, Market-street, Manchester	1
W. H. Vaudrey, Solicitor, 9, St. James's-square, Manchester	1
Arthur B. Holmes, Engineer, 1, Crosshall street, Liverpool	1
J. Clough Vaudrey, Engineer, 1, Crosshall-street, Liverpool	1
J. F. Albright, Engineer, Mansion House Buildings, London	1
R. Evelyn B. Crompton, Engineer, Mansion House Buildings, London	1
Wm. A. Ryle, Engineer, Chelmsford	1

The first Directors are R. E. B. Crompton, J. F. Albright, A. B. Holmes, and J. C. Vaudrey, who are to occupy their seats for seven years from the date of registration. The qualification is £100 for each Director. By clause 3 of the Articles, Messrs. Holmes and Vaudrey are appointed managing directors, and can only be removed by the shareholders at a general meeting to be convened under table A.

NOTES.

CABLE REPAIRED.—The cable between Trinidad and Demerara has been repaired.

CABLE INTERRUPTED.—The cable between Guernsey and Alderney is interrupted.

OLDHAM.—The Corporation of Oldham have decided to light the Town Hall, the Municipal Picture Gallery, and the School of Art and Science with electric light.

PERSONAL.—We are informed that Mr. Bernard Drake, of the firm of Drake and Gorham, 2, Prince's Mansions, Victoria-street, S.W., has been appointed electrical engineer to the Bank of England.

AWFUL!—An American inventor, who has been devoting his attention to electric railways, has recently mentioned that he has now nearly *two thousand* claims pending before the United States Patent Office.

NEW CABLE SHIP.—Messrs. Thompson and Son, of Sunderland, are about to launch a cable ship of 200 horse-power, which has been built to the order of a firm at Milan. She is 250ft. in length, carries three cable tanks, and is lit throughout by electricity.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending December 10th were £3,665, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

COLONIAL CONFERENCE.—The Secretary of State for the Colonies has proposed that a Colonial Conference shall be held in London early in 1887, when among other things the delegates would consider the whole question of postal and telegraphic communication with our colonies.

TELEPHONIC "TOLL" LINES IN THE STATES.—It is stated that the American exchanges which have introduced the "toll" system on any large scale find that it pays them well to cultivate this class of business, as these lines have a far lower ratio of expense to earnings than is the case for ordinary exchange lines.

BRADFORD.—During the late bazaar at St. George's Hall, Bradford, the buildings were lit with arc and incandescent lamps by the Woodhouse and Rawson Electric Contract and Maintenance Company (Limited), of Lancashire, Yorkshire, and Cheshire. A very good effect was obtained by 30 lamps which were used for lighting a Christmas tree.

TO PERSONS ENGAGED IN THE ELECTRO-PLATING INDUSTRY.—We are requested to state that at Prof. S. P Thompson's lecture at Finsbury Technical College, on Thursday, December 23rd, on "Dynamo Machines for Electro-Plating," free admission will be given to any person engaged in the electro-plating industry who will apply beforehand for a ticket of admission.

THE TELEPHONE IN BELGIUM.—We have received a copy of "La Téléphone Privée en Belgique," by M. Charles Mourlon, a book of fifty pages, containing very numerous illustrations, and giving a very complete account of the rise and progress of telephony in Belgium—more especially in connection with private lines, which are very numerous in some of the manufacturing towns of the country.

TELEPHONING OPERA AT LISBON.—The Lisbon Telephone Exchange have recently made arrangements by which their subscribers, for certain extra payments, are "put through" to the San Carlo Theatre, and are thus enabled to listen to the opera from their own residences. Special precautions are taken to secure the most perfect transmission, and the results have proved highly satisfactory.

TEMPORARY INSTALLATION.—On the occasion of a bazaar held on the 8th inst., at the Town Hall, Saffron Walden, the building was lighted by 30 Woodhouse and Rawson 16 candle-power 50-volt lamps. The current was supplied from an Elwell-Parker dynamo, driven by a twin-cylinder portable engine placed in a yard near by. The arrangements were carried out by Mr. Arthur Barrett, electrical engineer, of Saffron Walden.

FACTORY LIGHTING AT LONDONDERRY. — Mr. A. W. Richardson, of the Anglo-American Electric Light and Engineering Works, Stretford-road, Manchester, has recently completed an installation of 80 twenty candle-power incandescent lamps in the laundry department of Messrs. Welsh, Margetson's shirt factory, Londonderry. A "Richardson" dynamo, H type compound-wound, is employed, giving 110 volts and 55 amperes, at a speed of 440 revolutions per minute.

ELECTRIC CLOCKS IN VENEZUELA.—An export house in Stuttgart has just supplied to the town of Caracas, in Venezuela, a number of clocks for the public streets. On account of frequent earthquakes, clock towers are not advisable, and since the clocks must be placed low, a comparatively large number is required. Among the clocks sent out is one with a dial 13ft. in diameter. All the clocks will be worked electrically, and illuminated at night with the electric light.—*Industries.*

THE GREAT STORM.—Although the highest wind velocity recorded in the United States during the recent storm did not exceed forty miles an hour (while on its arrival in this country some of the gusts had attained a velocity upwards of 50 per cent. higher), yet very great damage is reported to have been caused to the telegraph wires in the Eastern States. In New York local communication was entirely disorganised. It is, however, believed that many of the wires were not broken by the wind but by the remarkably heavy rain which fell during the storm.

"THE NEW YORK HERALD."—According to an American journal, although Mr. James Gordon Bennett has been absent from the States for several years, he yet continues to perform the actual work of editor-in-chief of the *New York Herald.* Every morning, in whatever part of Europe he may happen to be, so long as a telegraph office is within reach, his second in command cables from New York a complete summary of the news of the previous twenty-four hours. Mr. Bennett then cables his comments, opinions, instructions, or advice. This service is said to cost—or at least to be worth—about £25,000 a year.

A CHURCH STRUCK BY GLOBULAR LIGHTNING—During the severe storms of last week at the village of Bradninch, Devonshire, the church tower was struck by lightning. Very serious damage was done, the tower being shaken to its foundation and cracked throughout one-third of its length; one of the pinnacles fell through the roof, and stones from the top of the tower were hurled through cottage windows at a considerable distance. This case is an interesting one, as from the description of an eye witness there can be no doubt that the destruction was due to a discharge of globe lightning. Balls of fire are described as whirling around the summit of the tower for a second or two, and disappearing with a tremendous explosion.

A NEW TERM REQUIRED.—No very satisfactory term exists at present by which to distinguish in a dynamo the diameter of the space between the pole-pieces *minus* the diametrical cross-section of the iron in the armature. Upon the suggestion of M. Cabonellas, the French have recently adopted the phrase

Digitized by Google

entre-fer for this purpose, and nothing better could be wished for; it is unfortunate that a literal translation does not suit our tongue, nor is "intraferal space" much better. The expression "air space," which is often used, is not only inexact, but is liable to lead to confusion with the mechanical "clearance." If, however, "air-space" is permissible at all, why not use "diamagnetic space," which is at least equally exact and not so liable to lead to confusion ?

THE POSTAL TELEGRAPH SERVICE.—On Tuesday evening a meeting of the Exeter telegraph clerks was held for the purpose of considering the evidence that would be required by the executive committee to lay before the Royal commission of inquiry into the working of the Civil Service. It was stated Mr. Fawcett's scheme, although intended to have greatly benefited telegraph clerks, had practically failed, through the retention of the system of classification and from the greater portion of the higher appointments being given to the postal branch. A committee was appointed to obtain accurate statistics from the surveyor. Resolutions were passed to the effect that every legitimate means should be used to obtain a full inquiry into the many grievances of which the clerks had to complain.

AN ELECTRIC LOW-WATER ALARM.—An electric low-water alarm, based upon a very simple principle, has recently been described before the American Institute. The apparatus consists of two gauge-cocks, a water gauge, a mercurial thermometer, a couple of Leclanché cells, and an electric bell. Two wires are inserted in the thermometer tube, and are connected with the battery and the bell. As the water in the boiler gradually lessens, steam comes down through the upper arm and gauge glass, and when a certain level is reached it enters also through the lower arm. Being hotter than the water, the increased temperature of the steam expands the mercury in the tube and closes the circuit. The bell then continues to ring until sufficient feed-water has been supplied; the feed-water being cooler, the mercury contracts, the circuit is broken, and the alarm ceases.

THE BRITISH ASSOCIATION.—A final meeting of the local executive committee was held at Birmingham on Wednesday, the Mayor (Alderman Martineau) in the chair. Reports were received from the exhibition sub-committee and from the local officers, from which it appeared that the exhibition yielded a surplus of £5,200. After defraying out of this sum all expenses connected with the meeting of the association in Birmingham, there remained an available surplus of £1,311. 1s. 5s. It was resolved that this sum be devoted to the provision of a permanent record of the meeting of the association in Birmingham, and of the exhibition to which it gave rise, by the purchase of a collection of illustrations of art in the Birmingham metal work exhibition at Bingley Hall, to be placed in the museum and art gallery, and that a select committee be appointed to make the necessary purchases.

UNDERGROUND WORK IN THE STATES.—At Boston the Telephone Company has commenced putting its wires underground of its own free will. A conduit to take 600 wires has been laid along some of the principal routes. The system adopted is that of creosoted wood troughs, together with a protecting coating upon the cables themselves, consisting of lead, alloyed with a little tin. This is the plan which has so far given very favourable results at Brooklyn, where it has now been in use for over two years. When the work at present contemplated by the Boston Company has been completed, some of their lines will run underground for a continuous length of over three miles. This is, we believe, a greater distance than any hitherto undertaken for similar lines on exchange service. It is to be hoped that the results will prove to be satisfactory. It may be added that by the end of the year over 1,500 miles of underground cable will have been laid in Boston.

TELEGRAPHS IN CHINA.—During the hostilities with France in 1884, the Celestial Government appears to have become aware for the first time of the fact that by the aid of the telegraph it is possible for a central administration to keep a much firmer control over provincial authorities. This fundamental fact having once been realised, the authorities are busily engaged in extending lines in all directions between Pekin and the great provincial towns. The material is all bought either in this country or in Denmark, but the work of construction is carried out almost entirely by the Chinese themselves. The first lines were built by Danish engineers and workmen, but the Chinese proved themselves such apt pupils, that in a very short time they felt competent to dispense with the aid of the Danes. It may be hoped that the manifold advantages of telegraphs will become so evident to the Chinese as not only to induce them to extend the wires throughout their vast and populous Empire, but also to pay some little more attention than they have ever yet done to the many other little dodges which outer barbarians would be only too pleased to put them up to.

TELEGRAPHS IN QUEENSLAND.—We have received the Report of the Post and Telegraph Department of Queensland for the year 1885. The number of telegraph offices in operation at the close of the year was 259, of which 36 had been established during the previous twelve months; 12,608 miles of wire, and 7,537 miles of posts had been erected, while 3,006 miles of wire and 1,567 miles of posts were in course of construction. The gross revenue amounted to £99,980, and the total expenditure to £92,932. The expenditure for maintenance and repairs of lines during the year amounted to £5,480. The total amount expended in construction of lines up to the end of last year amounted to £599,453. Iron poles are very largely employed, and give great satisfaction; in certain districts they are frequently bent by the force of the gales, but it is stated that they can be straightened again without difficulty. In October last quadruplex working was established between Brisbane and Sydney, and another quadruplex line will shortly be worked to Bowen. Two or three lines are also working duplex. The Department has established four telephone exchanges, of which Brisbane has 356 subscribers, and the others about 50 each.

MOTORS FOR PASSENGER LIFTS.—The use of the hydraulic system for working passenger lifts has given such excellent results in practice, and has so much to recommend it on the score of safety and trustworthiness, that it would scarcely be wise to recommend its replacement by purely electrical methods. But although the lifting force may still be obtained by water-power, there is no doubt that in future, whenever the distribution of power by electricity shall have become an accomplished fact, electromotors will be very largely employed for raising water for this and other purposes wherever the required pressure is not obtained directly from the water mains. The ability to dispense with the steam or gas engine, at present required for this purpose, would undoubtedly lead to an enormous increase in the employment of these convenient appliances. When once the required current is available, all the arrangements can easily be made absolutely automatic. The motor can be set to fill the tanks to a required height, then to automatically stop running until the water has fallen to a certain level, and then again coming into action. A similar arrangement is already

Digitized by Google

in use in some of the American cities, and works with perfect success.

"THE PEACEMAKER."—One of the most striking illustrations of the uses of electricity in modern naval warfare is to be found in the submarine boat which has recently attracted much attention in New York Harbour, and which has been christened "The Peacemaker." Originally the intention was propel the boat by electricity, but the trials are said to have been not altogether satisfactory, and soda motors have for the present been substituted. The fault, in all probability, lay with the accumulators, and we have little doubt that eventually electricity will be found to be perfectly adapted for the purpose. In the meantime the boat is of course lit throughout by incandescant lamps, and provided with means for firing torpedoes by electricity. The special novelty in the electric arrangements consists in the device whereby the torpedoes are attached to the keel of the ship which is to be destroyed. Two torpedoes are connected to the same cable, through which also four insulated wires are led within the boat. The current passing through one pair of wires traverses the coils of a powerful electro-magnet whose poles are outside the shell of the torpedo. A cork float around the same end causes the apparatus to tend to float with the poles upwards. Thus on diving underneath a hostile vessel, the torpedoes, being liberated, immediately rise upward and grip the iron keel; they can then be fired from a safe distance by means of the second pair of wires. A false wooden keel would, however, considerably diminish the terrors of this formidable weapon.

CHARGE OF ELECTRIC LIGHT APPARATUS IN HER MAJESTY'S SHIPS.—The following alterations are to be made in the Queen's Regulations with respect to the charge of electric light apparatus in Her Majesty's ships: The electric light apparatus, so far as regards the lamps, projectors, and conducting wires, is for store purposes in charge of the gunner, or the officer in charge of gunner's stores, except in troop or other ships which bear neither torpedo ratings nor gunner; in these ships the engineer officer is to have charge of the whole of the electric light apparatus and stores. The dynamos, and engines for driving them, are in charge of the engineer officer, who is responsible for their mechanical and electrical efficiency. The torpedo officer is to be responsible for the efficiency of all electrical circuits outside dynamo terminals, and for the management of the internal, search, yard arm, and other electric lights; but in ships where there are torpedo ratings, and no torpedo officer, the captain is to nominate the fittest person to perform the above duty from officers who have gone through a lieutenant's short course, or sub-lieutenant's course in the torpedo school. The search lights should be frequently exercised to instruct the officers and men in their capabilities for defence against torpedo boats, directing the fire of guns, and signalling purposes, under the direction of the torpedo officer or the officer nominated, and the particulars of such exercises are to be inserted in the half-yearly report of torpedo practice.

THE COST OF ARC LIGHTING.—On Friday evening last a lecture was delivered in the Royal Institution of South Wales before the Swansea Scientific Society by Mr. Polyblank, foreman of the Swansea Harbour Trust Works. In the course of his address Mr. Polyblank quoted the following figures as representing the actual working cost of an arc lighting installation at the works of Messrs. Kitson, the well-known locomotive engineers of Leeds. The installation consists of a No. 7 Brush dynamo supplying twelve arcs and a No. 5 machine supplying six arcs, the armatures being of the obsolete type. Each machine is coupled direct to a Parsons high-speed engine; these have now been running for over five years at an extremely small cost for repairs—in fact, all that has been done to them has been to let up the crank-pin bearings once a year. The repairs to the dynamos have been of an equally negligible character, and only one pair of brushes has been used per annum. There is no vibration when running, and no foundations were put in. The plant is in charge of a labourer, who supplies the oil required once a day, and has practically nothing further to do. As to the cost, using positive carbons at 3d. per foot and negative carbons at 1½d. per foot, in 16 hours 2ft. of positive and 1ft. 2in. of negative are consumed. This makes the cost of carbons per lamp per hour 0·48d., the boiler evaporates 9lb. per lb. of coal at 6s. per ton, and the Parsons direct acting engines use 40lb. to 50lb. of steam to the actual horse-power; this brings the cost of fuel to 0·16d. per lamp per hour. The oil used per 8 hours run in the two engines is two pints at 2s. 6d. per gallon, the water costs 6d. per 1,000 gallons, and the attendant gets 18s. per week. Summing up the working expenses on the above basis we get for a 60-light installation:—carbons, 0·48d.; fuel, 0·16d.; water, 0·03d.; oil, 0·09d.; attendant and repairs, 0·24d.; a total of 1d. per lamp per hour for working expenses. Messrs. Kitson, in making the comparison between the economy of electric light over gas, state that in Leeds gas costs 1s. 10d. per 1,000 cubic feet, No. 3 burners being generally used at the works, which are said to give 16-candle light and to use 3 cubic feet per hour; it therefore requires 125 burners to give the same light as one arc lamp, and adding one-sixteenth for rent of meter, the result is a working cost of 8¾d. per hour for gas to give the same light as afforded by one electric lamp.

ARAGO.—Next year being the centenary of the birth of François Arago, a movement has been set on foot in France for the purpose of raising a national subscription to erect a statue to his memory. It is proposed to place the statue in the centre of the large open space outside the Paris Observatory, and M. le Contre-Amiral Mouchez, director of the Observatory, has been appointed president of the committee which has taken the work in hand. In France Arago is honoured not merely as a *savant* but equally as a statesman and a patriot. He was undoubtedly a man of wide sympathies, possessing, at the same time, in an eminent degree, that quality of solid practical wisdom which is not always conspicuous in the French character. By an exceptional suspension of their rules Arago was made a member of the Académie des Sciences at the age of 23. This distinction was conferred upon him on his return from a geodesic mission in Spain and the Balearic Isles, where he had been absent three years, and which had yielded results of the highest importance to our knowledge of the figure of the earth. In 1830 he was appointed permanent secretary to the Academy. In this capacity he displayed a singular unselfishness and enthusiasm in assisting to the utmost of his power to further the labours of other workers in the field of science, and his correspondence extended to almost every man of any claim to scientific distinction in Europe. In the early days of telegraphy he vigorously and successfully protested from his seat in the Chamber of Deputies against the intention of the Government to prohibit the employment of the electric telegraph in France, except for State purposes. The French are fond of claiming for him an important share in the discovery of the principles upon which the telegraph was shown to be a practicable idea—but this claim is of a somewhat shadowy character. As an electrician his name is most widely known in connection with the experiment which led to the discovery of the "damping" action of a copper disc upon the vibrations of a magnetised needle, and for which an explanation was afterwards found by Faraday. Hence Arago

Digitized by Google

has probably a prior claim to stand sponsor to that troublesome and useless phenomena of induction which is now attached to the name of Foucault. Faraday's title being, however, equally good, clearly the phenomenon should have been christened the Farrago. Arago was for a long period President of the Municipal Council of Paris, and exerted himself on behalf of numerous measures for the amelioration of the moral and physical condition of the lower quarters of the town. At his suggestion the *Proceedings* of the Academy were first made public, and the *Comptes Rendus* was commenced. After the revolution of 1848, he became a member of the Provisional Government, as the Minister of War and Marine. During his short term of office he secured the abolition of slavery in the French Colonies and of corporal punishment in the fleet. Refusing to take the oath of allegiance to the second Napoleon, he lost almost his entire fortune, and was exiled from his native land. In 1853 he died. It is well that his memory should be cherished in the France of to-day.

ELECTRICITY FOR THERAPEUTICAL PURPOSES.—The following paragraph appears in the *Hampshire Telegraph* for December 11. We trust that our readers will not neglect to read it from beginning to end, for it is much too good to be lost. The "heavily charged" reporter discovering that he could still sit down and even read and write "without the slightest inconvenience" while sublimely conscious of the fact that he was "renewing vitality" is a really touching picture:—"The public of Portsmouth and vicinity are indebted to Captain Arthur Byng for placing electricity, for the alleviation and cure of all kinds of nervous diseases, easily, cheaply, and safely within their reach. We understand that Captain Byng has made this science a special study for some years past, and he has, after numerous experiments, fitted rooms with appliances that will enable electricity to be taken with perfect ease by any number of people at the same time. The rooms are situated at 23, Landport-terrace, and being quite close to the King's-road Tramway Junction they are easy accessible from all parts of the borough. They are comfortably furnished, and are situated on the ground floor so as to be on a level with the street and obviate the climbing of stairs. From a personal inspection we are enabled to speak of the complete success attending the various methods by which electricity is administered. There is no occasion to take off even outside wraps, and the current may be taken either sitting or standing. A number of regulators are placed in the room, which are worked with the utmost ease and accuracy by the patients themselves, so that they actually regulate the force of the current themselves and take it any strength they like. They are also enabled to instantaneously diminish the strength of the current as they wish. Captain Byng claims no new method of generating electricity, as his patent applies only to a new method—subdividing the current so as disseminate it equally throughout a room and administer it in various strengths to individuals sitting in that room. The positive and negative poles of a large coil are placed in connection with an insulated floor and an insulated ceiling, the floor consisting of sheet metal, and the ceiling consisting of wires broken by steel points, so that anybody placed on the floor of the room by that simple act is actually between the poles, and thus becomes charged with the electric fluid. Although heavily charged our representative ascertained that he could sit, read, write, or do any of the ordinary requirements of business without the slightest inconvenience, thus renewing vitality at the expense of no bodily labour. The medical men of Portsmouth, we may assume, will not be slow to appreciate the benefits thus placed within reach of a very large proportion of their patients, at whose disposal the rooms are now placed at most reasonable charges. We understand that the electrical rooms will be worked by a company of which Mr. J. Y. Martyr is the secretary, to whom the public should apply for all information. The rooms are to be opened from ten till four, and patients will be charged from one shilling to five shillings, according to the treatment they receive and the length of time they remain in the electrical room. On Tuesdays and Fridays it is intended to open the room from seven to nine p.m. for the benefit of the poorer classes."

ENGLISH *v.* AMERICAN DYNAMOS.—Some little time ago a contemporary journal, referring to a paper by Mr. Crompton which was published in *Industries*, made the remark that "at the present moment the most perfect incandescent light dynamos are produced in England; although as regards arc-lighters, we are in fairness bound to admit the superiority of the American designs." These views, which would probably be endorsed by most English electricians, do not, however, find favour with our friends across the Atlantic, and what is more serious they are prepared to bring facts—or at least figures, which after all is not quite the same thing—to support their own opinions. "So far as this statement (above quoted) refers to arc machines we are willing to accept it as true," says one of the American journals. But having given this proof of magnanimity they are confident that the remaining assertion can be "entirely refuted." The writer then institutes a comparison between the efficiencies claimed for certain English machines and those of the Weston and Edison machines, as determined by the tests at the Franklin Institute. It will be remembered that four Edison and three Weston machines were tested by the Institute in the autumn of last year, and undoubtedly these tests are among the most important on record. Our contemporary, however, proceeds with the comparison as follows:—"At full load the seven machines showed an average efficiency of 95·6 per cent., the lowest efficiency for any single machine being 94·45 per cent. Comparing the five best machines of different makers given in Mr. Crompton's table, we find their average efficiency to be only 93·4 per cent." At this point we must beg leave to enter a demurrer. Eight English machines are given in Mr. Crompton's table, including a small one, having an electrical efficiency of only 78 per cent. Had this last machine been included the average efficiency might have been induced to come down about 87 per cent. Although our contemporary has honourably declined to take full advantage of this opportunity, still we would submit that there is no reason whatever why five machines should be selected any more than four or three, especially as an efficiency of only 90 per cent. is claimed for the fifth machine. So far as a comparison of this sort can be made fair (or useful) at all, it will manifestly be fairest to select two machines by leading English makers for comparison with the two American types. Here the tables are turned, and we claim (at least an apparent) superiority of no less than 0·4 per cent.—the efficiency of the two English machines being each entered at 96 per cent. If it were worth while to pursue the subject further, we might point out upon the one hand that the highest of the tests of the American machines is marked "unofficial" by the Institute, while upon the other hand the English figures are slightly discounted by the fact that the output of the dynamos in question is in each case somewhat higher than that of the American machines. But at the best a comparison of results taken with machines of different sizes, at different dates, under different methods, and by different people, cannot possibly afford room for the discussion of ratios differing less than one per cent., so that the whole argument is in reality futile. While, however,

Digitized by Google

we are ready to admit that the practical superiority of English built machines is to some extent an open question, there can, we think, be no question whatever as to which country has advanced furthest in the *science* of the dynamo.

THE ELECTRC LIGHTING OF RAILWAY CARRIAGES.—We are very pleased to see that the *Pall Mall Gazette* maintains its championship of the cause of the better lighting of railway trains with praiseworthy energy. A representative of the journal has recently interviewed the managers of several of the leading lines, and has investigated the arrangements adopted for lighting carriages with gas on the Pintsch system. This method has for some time been employed on the Metropolitan Railway; but, though far superior to oil, cannot, of course, compare with electric lighting. Mr. Scotter, the general manager of the South Western Railway, expressed himself strongly in favour of electric light (with which the South Western Railway has already obtained an extensive acquaintance for yard and station lighting, both with arc and incandescent lamps), but he considered that the cost was as yet too great for general use. The following is the account given by the *Pall Mall* of their interview with the general manager of the London, Brighton, and South Coast Railway:—"We all acknowledge that the lighting of our trains is not what it ought to be, confessed Mr. Allen Searle, the secretary and general manager, but the directorate have determined that something shall be done without delay toward the removal of the reproach. On the 1st January a great experiment will be begun in the illumination of twelve selected trains. Six of these will be lighted with oil under new conditions; and the other six will be illuminated by electric lamps. The oil lamps will be filled with colza oil carefully selected, and fitted with wicks of the best quality; the glass will be clear and kept well polished, and reflectors of a new pattern will be introduced. On the electrically lighted trains each compartment will be provided with one light of ten candle-power, and where two compartments are structurally one, care will be taken to dispose the lamps in a way which will avoid shadows. The electricity will be generated by the locomotive drawing the train. The resolution to try the six trains electrically lighted is the outcome of experiments which Mr. Stroudley, the locomotive superintendent, and Mr. Houghton, the electrician of the company, have conducted for two years past with a train running on the Crystal Palace and Croydon lines. The results of the lighting of the Pullman trains running between the metropolis and Brighton confirmed the directorate in its determination. The system of lighting by oil lamps cost £70 per train per annum. It is estimated that the lighting by electric lamps will entail an expenditure of £100 per train per annum, but it is hoped that the actual cost will fall below that. The electrical system thus experimentally adopted by the London and Brighton Company is, we believe, that of the Railway Electrical Contractors (Limited). In this company's plan the dynamo is driven from the axle of the guard's van by the momentum of the train and fills the accumulators while the train is in motion, and there is thus always sufficient light stored for the very longest stoppage. The whole apparatus is enclosed in a locked cupboard on one side of the guard's van, is quite automatic, requiring no care or attention, except now and then when one of the company's officers sees that the machinery is oiled. It was of this system that Mr. H. C. Calcraft, the assistant secretary of the Railway Department of the Board of Trade, wrote at the close of 1884: 'As far as I could judge, the problem of lighting trains by electricity which is generated by the momentum of the train itself appears to have been solved.'"

THE ISLE OF MAY ELECTRIC LIGHTHOUSE.—The electric light has just been formally installed at the Isle of May lighthouse. The power of the beam of light from the paraffin flame previously in use was equal to 9,500 candles, while that of the electric light now shown is equal to about 30,000 candles, or more than three times that of the intensity of the paraffin light, and can, if desired, be increased to 60,000 candles during fog. This beam of light is one of the most intense ever shown from any lighthouse, as all the latest improvements, not only in the electric but in the optical apparatus, have been combined at the Isle of May. The preparations, consisting of buildings, dioptric apparatus, steam engines, and other appliances in connection with the introduction of the electric light at the May, have been in progress during the past eighteen months, according to the designs and under the superintendence of Messrs. Stevenson. The buildings, which have now been completed by Messrs. Stratton, contractors, Edinburgh, consist of dwellings for the engineer and two additional keepers, an engine and boiler house, workshop, coal store, and other necessary erections. In the engine house there are two steam engines for driving the electric machines, each of 16 horse-power, made by Messrs. Umpherston, Leith. There are also in the engine room two electrical machines supplied by Baron de Meritens, Paris. Only one engine and one electric machine are as a rule used at a time; the spare engine and machine are provided to guard against accident, and unless when very foggy weather occurs, it will not be necessary to use the full power of both engines and electric machines. The electric machines are "alternate current" magneto-electric machines of the largest size hitherto made. The armature is driven by a belt from the engine, through a countershaft, at a speed of 600 revolutions per minute. The current is conveyed to the lighthouse tower, situate at a distance of 880ft., by copper rods 1in. diameter. These rods or conductors are placed in a groove, in a low wall of cement rubble concrete, which has been built between the engine house and the tower, and alongside of which a pathway has been formed. The engine house and tower are also placed in communication by telephone. The conductors are led up the tower to the lamps inside the dioptric apparatus. The electric lamps are of the most improved kind, one being always in its place inside the dioptric apparatus, while another is ready, with the carbons adjusted to the correect height, to be shunted into the focus of the apparatus when required. The carbons are 1½in. diameter, and have a small core of pure graphite running through the centre. These carbons are found to burn with great steadiness and regularity. It was originally intended to use continuous current electrical machines, but unlooked-for difficulties were experienced in constructing an arc lamp which could be relied on, and recourse was had to the alternate current machines of Baron de Meritens, as above mentioned. The dioptric apparatus is of a novel description, on the condensing principle so successfully introduced into the Scottish lighthouses by Messrs. Stevenson thirty years ago, and since then largely adopted in other lighthouses. The May apparatus is so designed as to give a group of four flashes in quick succession, with intervals of darkness for thirty seconds, and condenses the light which would spread over 45deg. into 3deg. or fifteen times. The apparatus has also been arranged to admit of the beams of light being dipped to show near the lighthouse during dense fog, instead of being sent to the horizon. The condensing prisms circulate round the central apparatus by means of a machine driven by a falling weight. The dioptric apparatus was made by Messrs. Chance and Co., of Birmingham, and the revolving machine by Messrs. Milne, of Edinburgh, both from the designs of Messrs. Stevenson.

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 98.)

Since a flat coil of wire conveying a current behaves in all respects like a magnetic shell, having a south pole upon one face and a north pole upon the other, it follows that such a coil will be subject to the directive action of the earth, or of any other magnet, and will also be attracted by a magnet. Thus, if the north pole of a magnet be brought near to such a coil which is free to move, the coil will turn until its south face is presented to the magnet pole, and will then approach the magnet. The coil will come to rest finally in the plane of the magnet's equator.

Fig. 7 shows the lines of force, as depicted by iron filings, due to a coil conveying a current and a magnetic pole which are attracting one another. Fig. 8 shows the lines of force when the current is reversed, so that the pole and coil repel one another. By remembering that there is tension along the lines of force and pressure perpendicular to them we can tell from the pictures the nature of the mechanical action.

Fig. 7.

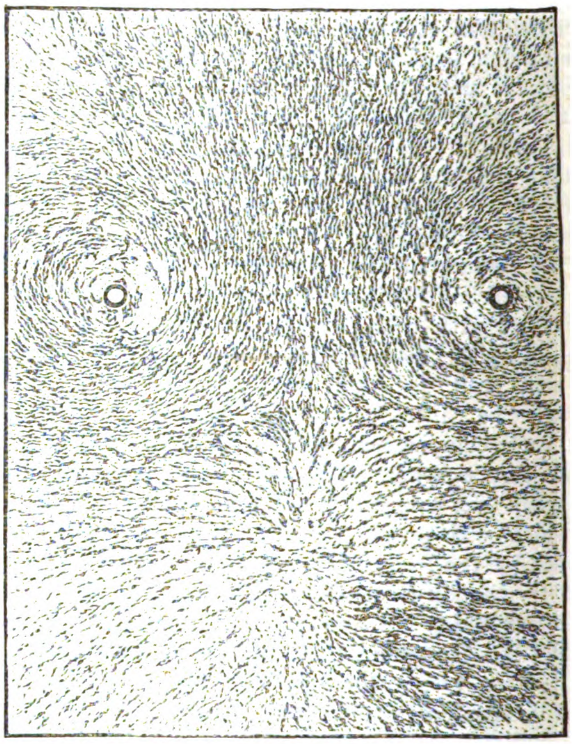

Fig. 8.

Def. The *positive direction* through a circuit conveying a current is the direction in which a right-handed screw would advance if rotating with the current.

A circuit conveying a current will tend to set itself in a magnetic field, so that the greatest possible number of lines of force pass through it in the positive direction.

In obedience to the same law magnets free to move in the neighbourhood of a current will tend to set themselves so that the greatest possible number of lines of force due to the magnets may pass in the positive direction through the circuit.

If the lines of force pass through the circuit in the negative direction the tendency will be to diminish their number, and, if possible, to reverse them.

This is the fundamental law of electro-magnetic action, and enables us to predict the behaviour of any wire conveying a current, if it is free to move in the presence of magnets or of other currents. The wire must form either a portion of a circuit or a complete circuit. In either case it will move so as to increase the number of lines of force passing through the circuit in the positive direction. If it is a straight wire of unlimited length which we are considering, we may suppose the circuit closed on either side of the wire, and the result will be the same. Hence it follows from the above law that parallel wires conveying currents in the same direction attract each other, and repel each other when they convey currents in opposite directions. A closed circuit will turn itself so as to cause as many as possible of the lines of force to pass through it in the positive direction, and will at the same time move towards the strongest part of the field for the same reason. In a uniform field a plane closed circuit will turn until its plane is perpendicular to the lines of magnetic force. Thus, under the action of the earth a coil in which a current is flowing will, if free to move, set itself with the axis of the coil parallel to the direction of the dip needle. A coil so suspended would serve as a compass and dip circle combined.

A very complete experimental investigation of the action of wires of various forms, conveying currents, upon one another and upon magnets was made by Ampère.

From what has been said it appears that a coil of wire, or solenoid, conveying a current behaves in all respects like a magnet upon bodies outside it. But the lines of force due to a coil are closed curves embracing the coil, and a needle suspended within the coil will set in the opposite direction to that taken up by a needle outside the coil. If, however, we employ a tubular magnet, and suspend a magnetic needle within the tube it will point in the same direction as a needle outside the tube and near its equator—that is to say, the north pole of the needle will point towards the south pole of the large magnet. In the magnet, as in the coil, the lines of force are closed curves passing from the north pole to the south pole through the air, but in the case of the magnet they return *within the substance of the steel.* Inside the tube the lines of force proceed as in the air outside the magnet.

On account of the similarity in the behaviour of a coil conveying a current and of a magnet, Ampère supposed that magnetism was due to electric currents flowing permanently around the molecules of the magnet. In a piece of unmagnetised iron or steel he supposes that the planes of these currents were arranged in all directions, so that the several molecules neutralised one another's action, and that the operation of magnetisation consisted in compelling the molecules to turn with their currents parallel to one another, the planes of these currents being perpendicular to the axis of magnetisation. In magnets which are not magnetised to the highest degree conceivable, the planes of the currents are not all

Digitized by Google

parallel, but have simply a tendency towards one direction. In the case of a solid bar magnet the molecular currents will neutralise one another at all points within the bar, and the effect will be the same as if a current flowed round the circumference of the bar. In the case of a tube the system will be equivalent to two equal currents flowing in opposite directions, one over the outer surface and the other over the inner surface of the tube. This will account for the behaviour of such a tube at all points, whether within or without the tube. Ampère supposed that the molecular currents experience no resistance, and thus when once set up continue permanently without requiring any source of energy for their maintenance. The theory does not explain why iron should lose all its magnetic properties at a bright red heat.

It has been stated that when a current flows through a coil of wire, magnetic lines of force will pass through the interior of the coil in the positive direction. If a bar of iron be placed within the coil the lines of force will enter the bar at one end, and, passing through the iron in preference to the air, will diverge from the other end of the bar. The end at which the lines enter will thus form a south pole, and that from which they diverge will form a north pole, the iron becoming a magnet by induction. If a steel bar be employed instead of an iron bar the induced magnetism will not be so strong, but the bar will retain its magnetism after the current has ceased. If the current be suddenly started and stopped a few times in succession, a steel bar placed within the coil may be permanently and strongly magnetised.

An electromagnet is a bar of soft iron surrounded by coils of wire. The bar is generally constructed so as to form three sides of a rectangle, in order to diminish the extent of the magnetic field formed in the air between the poles of the magnet.

The discovery by Davy and Arago of the temporary magnetisation of a soft iron bar by an electric current rendered possible a number of contrivances of the nature of electromagnetic engines. The most familiar of these is the common electric bell. Here an iron armature is attached to the electromagnet, but, in running towards it, breaks the circuit of the exciting current, thus destroying the magnetism when the armature is withdrawn by a spring, provided for that purpose, until by its return it again closes the circuit and excites the magnet. In all the electromotors of this class an iron armature is attracted by a magnet while moving towards its poles, but ceases to be attracted when it is receding. In this way work is done upon the armature while approaching the magnet, and is not absorbed again in its return. Continuous circular motion may be obtained by attaching iron armatures to a wheel, which as it revolves will carry them past the poles of the electromagnet, and by connecting a contact breaker with the wheel, so arranged that the magnet may be excited when one of the armatures is approaching its poles, but may cease to be a magnet when the armature begins to recede. Sometimes two magnets are employed, and armatures made to alternately approach and recede from their poles while the reciprocating motion is converted into continuous circular motion by cranks or equivalent contrivances. All the motors of this class are, however, very *inefficient*, and waste by far the greater part of the energy expended by the battery upon them. A better motor, somewhat resembling those just described, is made in small sizes by Mr. Apps. It consists of two small electromagnets, one of which is fixed while the other can rotate about an axis parallel to its cores and midway between them. The same axis is similarly situated with respect to the fixed magnet, and twice in each revolution the movable magnet has its poles just opposite those of the fixed magnet and within a small fraction of an inch from them. A commutator is connected with the rotating magnet and reverses the current in that magnet, so that when its poles are approaching those of the fixed magnet there is attraction between them, but when they are receding there is repulsion.

But it was Faraday's discovery of the tendency of a wire conveying a current to move across lines of magnetic force which led to the construction of the most efficient electromotors. Generally these instruments consist of an "armature," containing coils of wire, which is free to rotate in the strong magnetic field between the poles of a horse-shoe magnet. Sometimes iron is introduced into the centre of the armature, in order to concentrate the magnetic force. When a current passes round a coil in the armature this coil moves so as to place its plane at right angles to the lines of magnetic force, that the greatest possible number of these lines may pass through it in the positive direction. No sooner does it reach this position of equilibrium than the current in it ceases, and the energy of motion of the armature, as well as the action of the other coils, carries it over this "dead-point." Shortly afterwards the commutator, which is connected to the revolving armature, sends a current round the coil in the opposite direction to the first current, and the coil then moves on in order to set itself again in a plane at right angles to the lines of magnetic force, but now with its face reversed. In this way a continuous rotation is sustained in the coil, and work is done in driving the armature at the expense of the battery current, as will hereafter appear.

(To be continued.)

INCANDESCENT LAMP MANUFACTURE.—III.

BY J. SWINBURNE.

Amyloid Carbon.

Most makers of lamps are now agreed that Swan was right when he insisted that lamp carbons should be homogeneous and structureless. The most important homogeneous carbon by far is prepared from amyloid. Lane-Fox was the first to patent carbon made by carbonising parchmentised cellulose. He used vulcanised fibre, which is cellulose more or less parchmentised by chloride of zinc.

Swan, quite independently of Lane-Fox, worked out a carbon made from parchment paper or cotton.

The chemistry of the processes now to be described is somewhat obscure. Cellulose is nearly the sole constituent of such things as paper, cotton, linen, &c., and the object aimed at is to make a compound having the same chemical composition as cellulose, but very different physical characteristics. The process best known is acting by sulphuric acid. What is known as parchment paper, or vegetable parchment, is made by dipping blotting paper, or some loose-textured, unsized paper, in fairly strong acid. The acid seems to convert it into a soluble body, and partly to dissolve it, thus destroying the fibre. At this stage the action is stopped, and a tough, homogeneous, horny, semi-transparent substance is obtained. This can be made by a number of methods, and the substance seems to be the same though made by very different processes. The writer has called this substance amyloid, but he cannot now remember where he got the name from, or whether it is really a correct term. He thinks, however, it was given by Hofmann, and it may serve as a generic name for amorphous cellulose, however prepared.

The methods of making amyloid may be roughly divided into four classes. Cellulose may be treated with agents with a very strong affinity for water, such as sulphuric acid, zinc chloride, &c. It may be converted into a substitution product, as by the action of nitro-sulphuric acid, and the substitution product may be dissolved, and then precipitated in a non-fibrous form, and reconverted to its original chemical composition. Thirdly, cellulose may be acted on directly by a solvent, such as Schweitzer's magnet, and precipitated. Lastly, amyloid may be prepared by roundabout processes from such bodies as starch, seaweed, &c. This last is somewhat doubtful.

Cellulose has the composition $C_6H_{10}O_5$, or some multiple of it. It therefore consists of the elements of water combined with carbon. Of course it does not follow that the hydrogen and oxygen are combined in any way as water; but from the action of dehydrating agents it may be asssumed that that is to some extent the case. If cotton wool is put in sulphuric acid of the right strength, the acid seems to abstract water and form a compound which is partly soluble in sulphuric acid of that strength. If the action of the acid is then checked by immer-

Digitized by Google

sion in water, the compound seems to take up water again, and also to be precipitated. What the composition of the body is while partially dissolved in the acid cannot be known; but it is hardly likely that it remains $C_6 H_{10} O_5$ right through, and it is more likely that water is abstracted by the acid, and is replaced again on dilution. This is the more probable, as various bodies act similarly on cellulose which have no points of similarity among themselves except their strong affinity for water.

If the cotton wool were left longer in the acid, it would, on the addition of water, give dextrin, another substance with the same percentage composition as the original cellulose. The dextrin so formed is not quite the same as dextrin made from starch in the usual way, as it rotates the plane of polarised light to the left instead of to the right.

The sulphuric acid process may be described first, as it is by far the most important.

To make thread carbons, sulphuric acid is diluted to 1·64 s.g. Swan, in his specification 4,933, 1880, gives the best strength as 2 of oil of vitriol to 1 of water. This is somewhat weaker than 1·64, but the writer finds 1·64 best. The thread used should be of very loose texture, and still as even as possible. For carbons for ordinary 50 volt lamps knitting cotton is the best available material. No. 8 is a good size. For finer carbons embroidery cotton is better, as it is more even in texture. Swan mentions crotchet cotton as the best, but crotchet cotton is far too close in texture for use. No doubt the best material for 50 volt lamps would be embroidery cotton also, but unfortunately it is not made thick enough.

Some practice is necessary to enable any one to make carbons successfully by the sulphuric acid process. In fact, all the amyloid processes are very troublesome. In order to get an idea of the process, a short piece of knitting cotton may be dipped in the acid, and held up and watched. It will almost immediately begin to get transparent, and the little strands on the far side will become visible, making the thread look as if it were plaited. Any little lumps or irregularities on the outside will sink in, and the material will gradually become like an even string of raw white of egg. It will soon break by its own weight, and if then laid on a piece of glass it will gradually become liquid, the cellulose being converted into dextrin. If, at the moment the cotton appears thoroughly gelatinised, and before it is soft enough to break, it is dipped in water and washed, the action is checked, and the amyloid thread is produced. On immersion in water the outside of the thread turns white, just as white of egg does in hot water. The thread gradually becomes white and opaque right through. If it is now thoroughly washed in water, and then hung up to dry, with a small weight to keep it taut, it will shrink a great deal, and dry into a horny thread. If the thread is cut, or if the rough surface is polished, it will be found to be colourless and nearly transparent, looking like catgut. No sign of the original twist of the cotton should be visible.

The great difficulty is to immerse the thread in water exactly at the right moment. If it is immersed too soon the organic structure of the cotton is not completely destroyed, and if it is not immersed soon enough it falls to pieces, and is weak. If the acid is used weaker the thread is not so thoroughly acted upon.

In the laboratory the cotton thread may be wound on glass rods, or on frames, and dipped into the acid. In manufacture this does not give uniform results. The cotton thread is therefore passed continuously through an acid bath into water. Large drums of copper gauze are slowly turned in tanks of water. These are driven from the engine, so as to get even motion. A drum of knitting cotton is mounted so that it can unwind easily. The thread unwound from it goes under the surface of the acid, being made to pass under a sort of glass bridge. On emerging it rises over a very loose-running porcelain pulley, and then goes down into the washing tank, where it it is wound on the copper drum. The drum has a screw traverse motion, so that the material is wound on one layer deep. There must be very little friction in the system, otherwise the thread will break just before it gets to the water. The time of immersion of the thread is regulated by the length of the acid bath, the speed of the drum, and the distance between the acid bath and the washing tank. The writer prefers to put a glass T piece above the surface of the water. It is held in such a position that the thread passes through the cross-piece freely, and the shank is connected by a rubber tube to the water supply. The ends of the T are slightly contracted, so that the water squirts gently past the thread. By this means the action of the acid is suddenly and thoroughly arrested at a definite point. Sulphuric acid of this strength rapidly absorbs water from the air, so the bath must be covered over as well as possible, or else so little acid must be used that the bath has to be very frequently filled up with fresh acid.

The great difficulty is in always getting the same amyloid with certainty in manufacture. Probably it always contains a little unaltered cotton, some dextrin, and perhaps a little glucose. Slight differences of time of immersion, of strength of acid, or of temperature, will make very great differences in the carbons made by Swan's process. The writer finds the addition of metaphosphoric acid to the sulphuric acid beneficial. It seems to check the second action, or the formation of dextrin, so that strong acid may be used so as to convert the cotton thoroughly with less danger of the thread breaking just before immersion in the water.

Water is kept running through the tank with the copper drum, and when the drum is full it is put in another tank and left so that the thread may be very thoroughly washed. The least trace of acid left in the prepared thread is fatal, as it will act on it as the thread is dried.

To dry the prepared thread it is hung vertically or horizontally in such a way that it is always kept taut by little weights. It may easily be arranged zig-zag down the side of a room, passing over little loose wooden pulleys. One end is then fixed, and a weight is hung on the other. When quite dry and horny the prepared thread is taken down to undergo the next process, which is cutting down to gauge. This amyloid is exceedingly difficult to cut satisfactorily, as it takes the edge off such a thing as hard steel. It was only after great patience and many experiments that Messrs. J. W. Swan and Alfred Swan succeeded in cutting the material properly. A series of jewels like wire-drawing jewels are used; but the holes are cut differently. The holes are tapered one way only, so as to leave a sharp edge on one side, and the thread is drawn through, entering at the small end of the tapered hole. To give ease in starting, the dies are made to open, and when the thread is placed in them they are held shut by springs or are clamped. There is some trouble in getting such apparatus made well, and it is very much better to use dies that are not split. If the holes of the series decrease very little at a time, there is little chance of breakage of the thread if care is used. Of course the thread must be pulled through only one die at a time, not through five or six. Guides should be arranged so that the thread does not "chatter," else it may be cut all over little waves. For experimental work a die may be made by drawing out a piece of glass quill in the blow pipe flame, and breaking it at the narrowest part.

For flat thread carbons a loose texture braid is used instead of knitting or embroidery cotton. This flat braid is not generally to be got very fine; so that such carbons can only be used for 40 or 50 candle-power lamps.

The writer has had some beautiful fine flat braids made for him by silk spinners. Some of these were fine enough to be used for 10-candle 80-volt lamps.

After being cut down to the right size, the thread is ready for carbonisation.

It should at this stage be nearly transparent, like catgut, and there should be no traces of white fibres or of the original twist of the cotton visible in the centre.

This material is very hygroscopic, and swelling and contracting is the cause of some error in the surface of the carbon. If the material is damp when cut down it will make a thinner carbon than intended.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 10th inst. amounted to £4,440.

THE MAGNETIC CIRCUIT.

The following are the lemmas employed by Prof. Forbes* for obtaining the magnetic conductivity of different portions of the air circuit of a magnet, in order to calculate the total leakage:—

Lemma 1.—Between two opposed surfaces (Fig. 1) the conductivity may be measured by half the sum of the surfaces divided by the distance between them.

$$\kappa = \frac{\frac{1}{2}\,A\,B + C\,D}{E\,F} \times a$$

where a is the width perpendicular to the plane of the paper.

Lemma 2.—If the two surfaces are in the same plane (Fig. 2), and the air space does not exceed a certain distance, κ may be taken as

$$\kappa = \frac{1}{\pi} \log_e \frac{O\,B}{O\,A} \times a,$$

where O is centre line of the air space.

Whether this form or the next should be employed is a matter which must be left to the judgment of the investigator.

Lemma 3 relates to the same condition as the preceding, except that the air space is greater (Fig. 3).

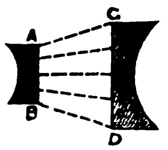

Fig. 1.

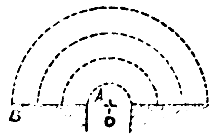

Fig. 2.

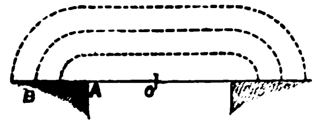

Fig. 3.

The formula in this case becomes

$$\kappa = \frac{1}{\pi} \log_e \frac{\pi\,.\,A\,B + 2\,O\,A}{2\,O\,A} \times a.$$

The difference between the values obtained by the two latter formulæ will be found, for medium distances, to be very small.

At a recent meeting of the Academie des Sciénces M. Leduc presented the following table, showing the induction which he had found to exist in the median plane between the poles of a certain magnet for different degress of exciting power and different distances between the pole-pieces:—

D centimetres.	Strength of field in C.-G.-S. units. 2 amp.	4 amp.	8 amp.	16 amp.	32 amp.
0·25	9060	13400	16930	19400	21100
0·50	5400	9200	12960	16130	18800
1·0	2780	5460	8440	12200	15830
2·0	1430	2820	4800	7320	10930
4·0	750	1500	2750	4200	6500
8·0	369	720	1370	2140	3400

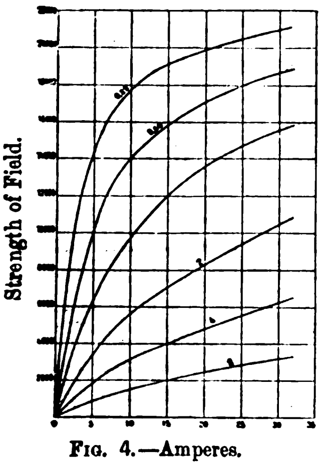

Fig. 4.—Amperes.

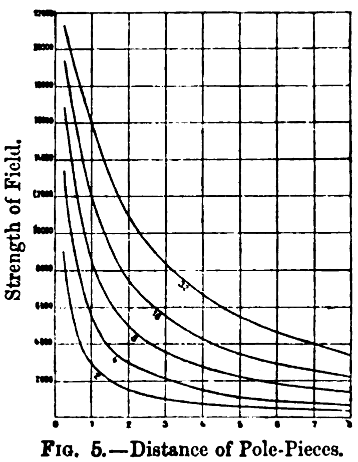

Fig. 5.—Distance of Pole-Pieces.

* See *Electrician*, Nov. 26, p. 63, Prof. Forbes's speech at the Society of Telegraph-Engineers.

Figs. 4 and 5 exhibit the results in graphic form. It would be interesting to see whether the recent investigations of Mr. Kapp, the Drs. Hopkinson, Prof. Forbes, and others had afforded the means for obtaining by calculation the remaining curves for varying distances of pole-pieces when one such curve is given.

At our request M. Leduc has courteously forwarded us a sketch (Fig. 6) (drawn to scale) of the magnet with which the observations were made, so that if any of our readers care to attack the problem the data are before them. We fear, however, that the task would be one of great difficulty, owing to the somewhat complex form of the magnet and the varying section of the iron. The magnet is provided with a cylindrical hole in the pole-pieces for the purpose of experiments on the rotation of the plane of polarisation. M. Leduc observed that his results were unaffected by the presence of iron in this space, a result which might be anticipated from the much greater total section of this part of the internal circuit. The

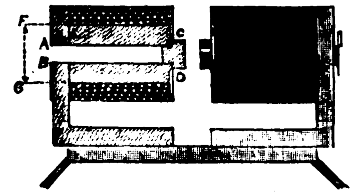

Fig. 6.

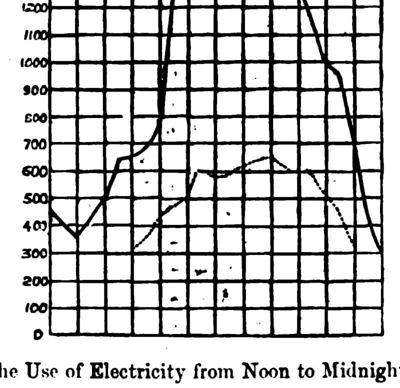
number of turns in each coil is 756. The dimensions are—E C, 28cm.; F G, 16cm.; C D, 7cm.; A B, 3·8cm. The width of the supporting frame may be taken at 14cm.

THE HOURLY VARIATIONS IN THE CURRENT FROM CENTRAL STATIONS.

The annexed diagram shows the hourly variation in the supply of current from a central lighting station at Boston.



The Use of Electricity from Noon to Midnight.

The installation consists of under 10,000 lamps, and the district chiefly consists of business premises, with a few private residences. The current in the daytime is chiefly required for running motors, the use of which is rapidly increasing. The full line shows the hourly consumption during an average weekday at this period of the year. The dotted line refers to a recent Sunday. It will be noted that during the whole period of supply the rate of change is remarkably rapid.

SENSE AND SCIENCE.

The saying that an ounce of common sense is worth a ton of learning, although a rash and unscientific generalisation, is one that finds acceptance not exclusively among the unlearned, whom it flatters. If we substitute insight for common sense, and add the qualifying observation that there is no necessary antagonism between natural gifts and acquired talents, the aphorism would pass muster unchallenged even in learned communities, whom it seems to disparage. As a proof of this, we need only cite the respectful but languid attention manifested by a scientific audience when listening to a merely learned discourse, and compare it with the lively interest awakened in them by a man of true insight, and, as the vulgar call it, common sense. We shall not be suspected in this journal of underrating knowledge, or of rating too highly the *un*common sense which is meant when we talk of common sense, and which is in reality Wisdom. But we confess to a share of the weakness of ordinary mortals, and are not ashamed to own that we prefer a sensible thing without learning to a learned thing without sense. Whether an ounce of common sense without any learning is worth a ton of learning without any common sense is a question, perhaps, hardly worth discussing; only one thing, indeed, can be affirmed of it with certainty, namely, that their respective owners will never exchange possessions—the one because he is too sensible to part with what he prizes most; the other because he is too foolish to desire what he needs most.

Some such reflections as these were irresistibly presented to our mind during the progress of the discussion of Prof. FORBES' notes on some magnetic phenomena at the Society of Telegraph-Engineers and Electricians last week. The notes were of a speculative kind, and having been the subject of thought rather than of experiment, were eminently calculated to fill up a gap by inviting the unpremeditated commentary of persons who had given any thought in the same direction. The circumstances of the evening, as explained in our last week's issue, being favourable to desultory talk, there was a good deal of it, and it took a form that manifestly was exceptionally interesting to the audience. The learned members, so to speak, dropped their mantles and talked like ordinary human beings, bringing their insight, or common sense, to bear upon problems which at other times they are accustomed to treat in a highly scholastic fashion. We give elsewhere a report of Prof. FORBES' notes, but for the present we desire only to remark on the suggestions they gave rise to. Clearly the train of thought which had carried him so far would have taken him a good deal farther. One speaker said as much, and asked the question, why not treat the two things—current lines of force and magnetic lines of force, current pressure and magnetic pressure—with which Mr. FORBES was dealing as fundamentally identical, when all the phenomena relating to them seemed so plainly indicated to be the same, only under different names? We did not understand this to imply any disrespect to Prof. FORBES' method, but rather as expressing the speaker's satisfaction that the tendency of thought, as betrayed in the professor's discourse, was taking the direction his critic desired.

The general drift of the discussion did, in fact, point to that conclusion. We do not say it is the right one; all we wish to point out is that it is the conclusion which insight and common sense have arrived at long ago, but which learning has not yet condescended to seriously or carefully examine. Common sense may be wrong in this particular, but it cannot be so wrong as some of the scientific dicta of the received text-books, some of which are redeemed from absurdity only by the transparent sincerity of their compilers. They have become saturated with the formulæ handed down to them, and for every fresh discovery or difficulty they invent fresh explanations on precisely the same lines. It is here where a grain of homely sense and a little exercise of the imagination would prove invaluable. But these qualities the average student has been taught to neglect, or at all events to exercise with misgivings. He finds it safer, consequently, to follow on the approved track, and it is certainly easier. Only the free lances of science venture on independent courses of their own, and are invariably treated as ignorant heretics for their pains.

This is a fate they deserve when they treat learning as of no account; but a similar and not less severe judgment should be passed on the man of learning who treats common sense as of no account either. We once surprised a young student trying to induce a suspended glass needle to point north and south by rubbing it on his coat sleeve, and we at once understood his stolid refusal to follow the text-book explanation of the action of a galvanic cell. His imagination had dissolved some of our theoretical fictions into practical impossibilities, and he was essaying a reconstruction on the basis of his own intuition. We do not know what came of his bit of

Digitized by Google

excited glass, which by some process of mental vision he had identified with the magnet; but we entertain the opinion that a man of that character is more nearly related to the Newtons and Faradays of the past than is the modern scientist who lets his imaginations rest in perpetual fallow.

We are not to be understood as reflecting on anything that transpired at the meeting to which reference has been made. Quite the contrary; the discourse and the discussion following it were most suggestive, and entirely of a kind we should like to more often listen to—although we confess to not understanding how Prof. FORBES is to obtain a field of force in the interior of his iron cylinder if wound like a Gramme ring, but with only one coil. Neither are we unmindful of the practical and, perhaps, necessary difference which will always exist between the analytical and the constructive intellect in man. Both have their special but distinct fields of operations. But they must not be confused the one with the other, much less the one for the other. It is possible to look so closely into a thing that you cannot see it—that is to say, cannot see the thing itself, but only its constituent parts. The man who can step back and look at it as a whole, if he has any real insight, will assuredly form a truer conception of it than will the mere analyst. It is given but to few men to be endowed with both these faculties in their highest development; but all men can try both methods, and our advice is, do not be too closely wedded to one method only. To tie yourself down to what you can tangibly handle, test, measure, and weigh, is, perhaps, the worst of all methods, resulting only in a barren array of figures, while somebody else, with keener perceptions and a wider range of vision, has already reaped the harvest.

AFTER THE ELECTION.

We have but a very few words to add to the remarks which were penned just before going to press, and immediately after the election proceedings at the Society of Telegraph-Engineers, last week. The delay which occurred in announcing the result showed that there must have been a good deal of what is called "cross voting," and that nothing in the nature of an organised effort to promote any particular "ticket" had been attempted. The patience with which the members waited for the result showed, on the other hand, that individually each and all of them were interested to learn it. We congratulate the members on this healthy sign of vitality, which, to our thinking, will tend to do the Society far more good than the rejection of a few deserving candidates can possibly do harm. The labours of the scrutineers may be expedited by adding still further to their numbers, and by preparing a methodical scheme of counting beforehand. We are quite aware of the objections and difficulties arising from submitting a larger number of names to be voted upon than there are men to be elected; but nothing can be so objectionable as the opposite course, and we trust that the one adopted last year and this will be steadily persevered in. As to the persons elected, we could have wished that the choice in some instances had been different; but the members, as a body, having expressed their wishes, we cheerfully accept the situation, and recommend all our friends to do the same. While it was our plain duty to give expression to the opinions of an influential section of the Society whose aims we cordially approved, it is equally plain that what we have to do now is to support its duly-elected officers in a loyal and generous spirit. The coming year may be an eventful one for the Society; and, under existing circumstances, it behoves us to spare no pains to bring it through the ordeal with dignity and credit.

CORRESPONDENCE.

COILS, UNITS, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think the interest of this matter justifies a few more words on my part, which I hope may be the last.

The arrangement of wires which I assumed agrees with that mentioned by Mr. Kapp in the first lines of his last letter. It does not seem to me that any approach to an accurate geometrical arrangement could be secured in any other way. With the wire wound as Mr. Kapp describes afterwards, it is clear that, if his rule is to be correct, each coil must touch the one below it only at the point where they cross, and must rest suspended in air throughout the rest of the turn. This cannot be. It will descend gradually into the groove, and after the half turn reascend on the other side. It would require a minute investigation to find out how it all really happens, and I think my remark as to the impossibility of securing an accurate geometrical arrangement is amply justified.

As to the change of figure of the section of the wire. Suppose you put a bit of soft wire in a vice and pinch it, you flatten it at the points of contact, and bulge it in the other directions. Here you have wire lying in a sort of long narrow vice, which compresses it (generally) at four points all along. Suppose that these yield in the least, the free parts of the wire will bulge, and the spaces will be more filled than if the figure were true. With very small wire a thousandth of an inch of such yielding would produce a considerable effect. It seems to me that such a pinch would be particularly liable to happen where two coils cross. In all this I only wish to illustrate my general opinion that the use of a mass of wire is not suitable for determining a cross-section accurately.

With respect to the units. Your correspondents all seem to think that Mr. Kapp's method is to enable them to get rid of C.-G.-S. But that is not so, at least according to your report. When your unit is 6,000 C.-G.-S. magnetic induction, all measures of magnetic induction must be made in C.-G.-S. as before, and then changed into the new unit. The only way of getting rid of C.-G.-S. is to adopt a similar system founded on other units, such as the foot-grain-second system which I mentioned before. I think we do better with C.-G.-S. as it is.—Yours, &c., R. H. M. BOSANQUET.

Dec. 12, 1886.

TESTING DYNAMO MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to Dr. Hopkinson's letter on dynamo testing, I may say that my article was in type before the Royal Society paper was published, and I would venture to suggest that much valuable technical information is lost when presented to the Royal Society. The paper of Drs. J. and E. Hopkinson hardly appeals to the students of pure science as much as it does to makers of dynamos. They very kindly sent me a copy of their paper when it was printed, but that was after my article was in type. This paper gives the data which I particularly desired. It seems from these very carefully made tests, that the very simple method described last in my article will be found quite accurate. The simplest case is that of a compound dynamo. To test such a machine, the normal electromotive force is put on the brush leads. The machine then runs at normal speed with a small current through the armature. The product of the back electromotive force and current then give the stray power, and this added to the shunt, main, and armature losses at any given load give the total loss in the machine. To be quite accurate the field should be a little more strongly excited, so as to get the full load electromotive force in the armature.—Yours, &c.,

JAS. SWINBURNE.

ELEMENTARY ELECTRICITY AND MAGNETISM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 10th inst., under the above heading, a paragraph on page 97 is devoted to the method of using

Digitized by Google

a sine galvanometer. The author seems to consider a sine galvanometer as an instrument of definite form, the coil of which is capable of turning about a vertical axis. Also he seems to think it essential that the coil should be placed in the same plane as the magnetic axis of the needle. Such limitations are quite unnecessary, for *any galvanometer* capable of being turned round the axis about which the needle turns can be used as a sine galvanometer, and the law is true whatever be the angle between the needle and coil provided this angle be constant during one set of experiments. The necessary and sufficient conditions are:—1st. The controlling field must be uniform. 2nd. The relative positions of the needle and coils must be the same in one set of experiments. The same restrictions as described by the author of the article are to be found in nearly all elementary text books which describe the sine galvanometer, hence students obtain wrong impressions therefrom.

An endeavour to correct these common ideas must be my excuse for troubling you with this note.—Yours, &c.,

T. MATHER.

A LITTLE PUZZLE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you kindly give me a little advice under the following difficulties through the correspondence columns of your valuable paper?

I have been trying to fit up an electric communication between my house and workshop, which are separated by a distance of fifty yards. I have erected a line wire of copper on insulators, and have placed bells and batteries at each end, with earth-plates consisting of galvanised corrugated iron, 24in. by 18in., buried in the earth 6ft. deep, with galvanised wire connections soldered to plates. Upon trying the current with Leclanché No. 2 cell, I was surprised to find neither bell would ring, so I put galvanometer in circuit, which gave a slight deflection, not nearly sufficient to ring a bell. By way of experiment I put two more cells in circuit, arranged first in series, then all in parallel, and to my surprise, the galvanometer showed exactly the same deflection as it did with the single cell. To prove where the fault lay, I attached an old rusty iron wire from the wires of each earth-plate, and each bell rang beautifully, which proved the fault to be in the plates. Now, what I should like to know is why are the plates at fault, especially when the earth is saturated with wet, as it is at this time of the year? All other telegraphic lines work with earth plates, and why will they not answer in my instance? Of course I could put an extra wire on, and it would work all right, but that would not be throwing any light on the difficulty, and I should still remain

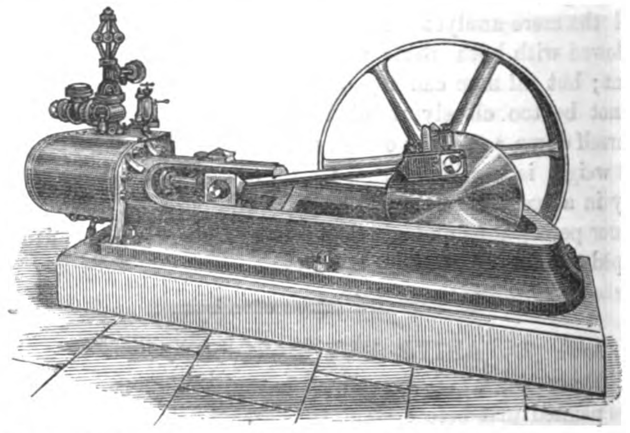
CONQUERED.

THE LIGHTING OF TAUNTON.

We have much pleasure in announcing that the Corporation of the Borough of Taunton has entered into a contract with Mr. Massingham, of Bath, to light the streets of the town by means of the Thomson-Houston arc light. The contract is signed for a period of seven years, but is terminable at the end of certain periods after three months' notice on either side. One of our representatives has recently visited Taunton, and inspected the progress of the work; Mr. Massingham at the same time courteously placed at his disposal a mass of information as to the financial aspect of the undertaking, the chief points of which will, at the present stage of public electric lighting in this country, prove interesting to a large number of our readers.

But before proceeding to these details it will be as well to give some description of the installation itself. The town of Taunton may be roughly described as consisting of three main streets, which meet in the centre at nearly equal angles; two of these are each about one mile long, while the third is much shorter. It is at, or quite close to, the point of intersection that the machines have been established. With a laudable desire to interest the local firms in his undertaking Mr. Massingham determined to place the order for both engines and boilers in the hands of Messrs. Easton and Waldegrave, of the Whitehall Ironworks, Taunton. The result has fully justified his selection. The engine is of the simple, non-condensing type, and works up to 40 indicated horse-power. It is of substantial design, and has a massive bed of the box girder type, with which the front cylinder cover and slide bars are in one casting, the latter being of bored pattern. The piston, slide rods, crank shaft, and all journals are of steel, the bearings being of phosphor bronze. All the moving parts are accurately balanced. A Pickering governor is fitted, and does its work thoroughly well, at a speed of 100 revolutions per minute. The power is taken from the fly-wheel, which has a diameter of 6ft. 2in., and drives on to a counter-shaft by means of a 12in. link leather belt.

The boiler, which is of the locomotive type, has an outside shell of steel; the firebox is of Lowmoor iron. The working pressure is 120lb. per square inch. Water is taken from the street mains into a large tank, and is thence supplied to the boilers by means of a feed pump. The boiler is in a separate room from that containing the engine and machines; but the length of the steam pipe does not exceed 8 or 10ft.



Non-Condensing Engine made by Messrs. Easton and Waldegrave, of Whitehall Ironworks, for the Taunton Installation.

There are at present in operation two 30-light Thomson-Houston dynamos, each giving a current of 6·8 amperes, and capable of working up to 1,500 volts. These machines are too well known to need further description here. Steps are now being taken to double the whole of this plant. Mr. Massingham is building a new boiler house and machine shed alongside of the present structure, but the whole of the additional arrangements will be carried out on the same general lines. In addition to the machines above mentioned there is an old-fashioned Edison dynamo with long magnets, giving 110 volts and about 50 amperes, for charging accumulators. These latter are used for lighting the Castle Hotel, which is close at hand, and is fitted throughout with 16 candle-power glow lamps. The distribution of light in the principal rooms of this hotel has been very skilfully carried out, and the whole installation is affording great satisfaction. When the extensions above referred to are completed, the incandescent plant will be increased to a capacity of about 150 sixteen candle-power lamps; but we shall not be surprised if at an early date Mr. Massingham finds it necessary to extend his operations considerably further in this direction. Something has been done in the way of running 16 candle-power lamps in multiple series upon the arc circuits, but the method has not been found altogether satisfactory up to the present time.

Coming now to the arc lighting as at present arranged, one of the 30-light machines is used for shop lighting and the other for street lamps. These machines have been running (under the present ownership) since May last, and under the superintendence of Mr. George Hooker, the electrician in charge, the work has been carried on entirely without hitch of any kind. It may be stated here that the town of Taunton is

Digitized by Google

really indebted for the electric light in the first place to the enterprise of Messrs. Laing, Wharton and Down, the well-known representatives of the Thomson-Houston system in this country. Having, at the invitation of Mr. Massingham, broken ground in the locality, the firm ran the plant for some time with the intention of forming a local company to carry on the undertaking. But negotiations on this head having fallen through, Mr. Massingham came forward and, taking the entire responsibility on his own shoulders, he bought the plant and set to work to make the thing a success. There can be no doubt whatever that electric lighting would rapidly extend from one end of the country to the other, and would stand on a much sounder and more permanent financial basis if a larger number of individuals could be found, like Mr. Massingham, to embark their own capital, and give their own time and attention to its development in their own locality, instead of allowing what is now a purely industrial affair to be carried out (or otherwise) by the inevitable limited liability company. It is only the present lack of confidence among those on the look out for investments for their capital, and work for their hands and brain, that prevents such comparatively small industrial undertakings from springing up in every market town of the country. And, after all, the lighting of a few hundred lamps amounts to but a small undertaking from an industrial point of view.

Returning to more technical matters, the circuits are, at present, seven in number, and measure about two miles in extent. But so far only the central part of the town has been reached; when the contract for the street lighting is carried into effect, the circuits will be increased to 12 in number, and five or six miles of wire will be in use. The street lamp posts, which are of good height, are now being erected by and at the expense of the municipality. The wire employed corresponds to No. 8 B.W.G. It is of American manufacture, and is covered with asbestos braid. It is supported by Johnson and Phillips's fluid insulators—undoubtedly a wise precaution. For leading-in wires a stranded cable (7/18's) insulated with india rubber is employed. The resistance of the mains is about 1·28 ohm per 1,000 yards, which gives a loss of 8·7 volts corresponding to about 59 watts over that distance.

Turning now to the contract for lighting the town, the principal clauses are to the following effect:—The contractor provides everything essential for the installation and maintetenance of the lighting, with the single exception of the supports for the lamps and wires, which are provided by the Council. All the machinery is to be in duplicate, and arrangements are to be provided for immediate substitution in the event of a break down. On the occurrence of such a break down the Council to have the right, if they think fit, of terminating the contract at twenty-four hours' notice. Otherwise the contract is only to terminate at the end of the third or fifth year, upon three months' notice from either party. Thirty lamps, each of 1,200 candle-power, to be lit every night for an average period of eight hours, the Council to have the right either to extend the period to ten or to diminish it to six hours, with a proportionate variation in the rate. For the eight hours' (average) service the Council agree to pay the sum of £652. 10s. per annum. Another clause provides that every lamp shall be examined, the carbons trimmed, and the globes cleaned daily. The remainder of the town will be lit by oil, the Council dispensing altogether with the use of gas for street lighting. The report of the committee, who were appointed by the Council to investigate the matter, shows that the total annual cost of lighting the borough by gas for eight hours per night, based on the average of the last two years, amounts to £1,316 (gas costing 3s. per thousand), while the estimated cost of lighting by oil and electricity (including a sum for depreciation of the posts, which were to be supplied by the town) was only £1,329, showing a saving of £13 in favour of gas. For this trifling addition to their outlay they would get an incomparably better light in the centre of the town, and in the outskirts one quite as good in every respect as at present. Before arriving at this conclusion the committee made inquiries respecting the success and public estimation of oil lighting, from the town of Winchester, where it is exclusively adopted. The reply received proving of a thoroughly satisfactory character, the report of the committee was at once adopted.

The charges made to the shopkeepers for arc lights are as follows: For four days of the week from dusk till 8 p.m., Thursdays till 5 p.m., Saturdays till 10 p.m., £13. 10s. per annum. There is a scale of charges for longer hours, running up to a maximum of £18 for lighting from dust to 11 p.m. all the year round. This charge includes the supply of carbons, and trimming and cleaning the lamps. A charge of £1 is made towards the cost of fixing each arc lamp. If preferred, six incandescents are substituted for the arc lamp, and in that case 15s. is charged on each lamp fixed, and the fittings become the property of the customer.

It only remains to add the following remarkably encouraging figures:—On May 1st the total rentals of the installation amounted to £300 per annum, and the working expenses to £400. On January 1st, when the town contract comes into operation, the rentals will amount to £1,300, and the working expenses to £800, while there is every prospect of still further extensions in the early future. We offer Mr. Massingham our sincere congratulations on the services which he—a non technical man himself—has rendered to the progress of electric lighting in this country by means of a little enterprise, combined with sound business management and a judicious absence of parsimony in the original laying-out of his plans.

A RELATION BETWEEN MAGNETISING FORCE AND CORE OF MAGNET.*

BY E. L. FRENCH, B.S.

It has seemed to me that a formula which would enable a man to state the greatest number of ampere turns that could be used economically on a core of given size, might have some practical value. By "economical" use, I mean that the strength of the magnet increases rapidly per ampere, up to this number of turns, in comparison to what the increase is with a little greater number. It will be seen later that we cannot say exactly what this number is, since the bends in the saturation curves are not sharp ones.

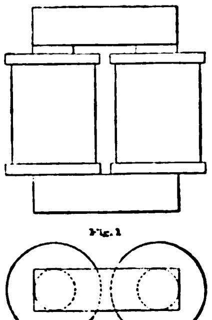


Fig. 1

The scheme of the experiment was as follows: To find the highest economical number of ampere turns for each of several electro-magnets, all of same type and material, and having cores whose diameters increase regularly by a small amount. To decide what was the highest economical current for each magnet (the turns being constant), by plotting a curve whose ordinates are proportional to strength of magnet, and abscissæ are proportional to amperes of current. Finally, to take these "highest economical currents" in amperes, and their corresponding diameter of cores in centimeters, and plot them for a final curve. The equation of this last curve will furnish a formula which gives us the diameter of core, when ampere turns are known, or gives the ampere turns when the diameter is known—provided the material and type is the same as in those magnets experimented upon. The type of magnets used is shown in Fig. 1, which gives plan and elevation. The cores are of circular cross section, and the armatures of square. Each edge of the cross section of armature equals the diameter of its corresponding core. Five such cores, with their arma-

tures, were made from patent cold rolled shafting, presented to the university by Jones and Laughlin, of Pittsburg, Pa., and used in a set of spools which would just admit of the largest core, as will be seen by the table of dimensions below :

Spools.

Internal diameter of tube.	Thickness of tube (brass).	Wire.	No. turns on each spool.
6·34 cm.	About 2 cm. ...	No. 10 copper wire, single wound, run ... through paraffin.	785

Cores. Diameter.		Length.	Armature. Section.		Length.
1·22 cm.	......	20·85 cm.	1·22 × 1·22 cm.	......	18·3 cm.
1·22	......	20 85	1·22 × 1·22	......	18·3
2·52	......	20·88	2·52 × 2·46	......	19·62
2 52	......	20·88	2·54 × 2·46	......	19·62
3·76	......	20·82	3·80 × 3·74	......	20·90
3·76	......	20·82	3·80 × 3·74	......	20·90
5·03	......	20·82	5·10 × 5·02	......	22·04
5·03	......	20·82	5·10 × 5·02	......	22·04
6·34	......	20·88	6·32 × 6·30	......	23·90
6·34	......	20·88	6·36 × 6·30	......	23·92

Armatures of section 2·52 × 2·46 and 2·54 × 2·46 were steel, Jones and Laughlin's not having the cold-rolled shafting on hand. The extreme length of the spools was about 1 cm. less than the length of cores, to admit placing a narrow coil of fine wire close around the pole above the spool. The surfaces of the armatures were planed smooth and the ends of cores squared off (in a lathe) at the Sibley College shops.

In all tests made by me, the magnets were set up as shown in Fig. 1. In making experiments on the magnets to determine the highest economical number of ampere turns, the connections were made as shown in Fig. 2. The current was

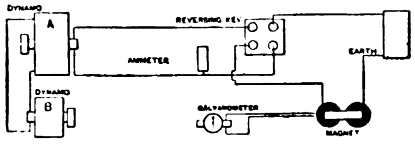

Fig. 2

furnished by a Gramme dynamo, A, which had its magnets magnetised by a small Weston, B. A Siemens and Halske electro-dynamometer was used to measure the larger currents, and a Thompson ammeter for the smaller ones. The galvanometer was a heavy astatic one. The ammeter was placed near the reversing key, and the galvanometer was on the farther side of the same room. The magnet was placed in a distant part of the laboratory, while the dynamos were still farther away. The narrow coil of fine wire placed close around the pole was in circuit with the galvanometer.

Now, a reversal of the magnet poles, by reversing the current through the magnet, causes a deflection of the galvanometer, since an induced current is generated in the narrow coil at the instant of reversing. The sine of the half angle of deflection is proportional to the strength of the magnet. In my experiments the angle was small, and I have used the double deflections—*i.e.*, the difference of the right and left deflections as read from scale.

The induced circuit was always broken, except at time of reversals, and till the galvanometer reading was taken. This prevented, to a great extent, any disturbance of the galvanometer by fluctuations of current from the dynamo. It was convenient to place the key for closing the induced circuit upon the table that supported the telescope and scale for reading the galvanometer ; hence a peculiar form of key was made that could be closed by pulling a cord, while standing at the other side of the room near the reversing key and ammeter.

Let us suppose the dynamos running, and the ammeter indicating a steady current ; also the galvanometer at rest. I stand by the reversing key, note the reading of the ammeter, close the induced circuit (by means of the cord), reverse the current, and step quickly across the room to read the first swing of the galvanometer.

Four such reversals were made with each current, and the mean of the two double deflections used. Thus we have strength of current, and a number proportional to strength of magnet. The saturation curves for the different magnets are shown in Fig. 5.

To determine what the highest economical current is for a magnet, I drew a line coinciding with the rapid rise of the saturation curve, and another with the nearly horizontal part of it, and produced them till they intersected, then bisected the angle thus formed. This bisecting line cuts the curve at a point midway between greatest economy and greatest waste of current. This method gives similar points in each curve. Ordinates of points thus determined are given below, opposite their corresponding dimeter of core.

Current.	Diameter core.
·35 am.	1·22 cm.
·55	2·52
·83	3·76
1·37	5·03
1·52	6·34

Plotting currents as abscissæ, and diameters as ordinates, we have the "final curve," also shown in Fig. 5. The equation

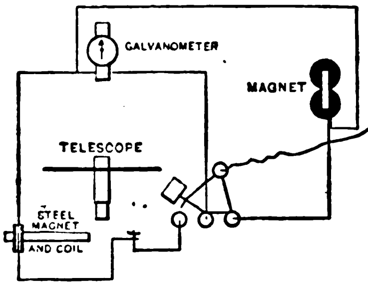

Fig. 3

of this curve is $y = 8{\cdot}8868\ x^4 - 25{\cdot}80116\ x^3 + 22{\cdot}07239\ x^2 - {\cdot}93553\ x - {\cdot}22125$; but the following simpler equation gives close results, when values of x from the above table are substituted :—$y = 9\ x^4 - 26\ x^3 + 22\ x^2 - {\cdot}7\ x - {\cdot}22$.

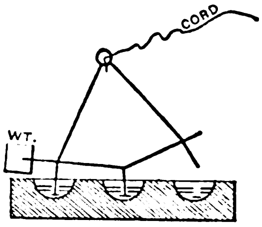

Fig. 4

If we substitute for x ·83 (see table) we have 3·76 cm. for the diameter of core which would be brought up to greatest economical strength by ·83 x 1570 ampere turns. Again, if we substitute a value for y and solve for x we must multiply the value of x by 1570 (the number of turns on spools) to get the ampere turns.

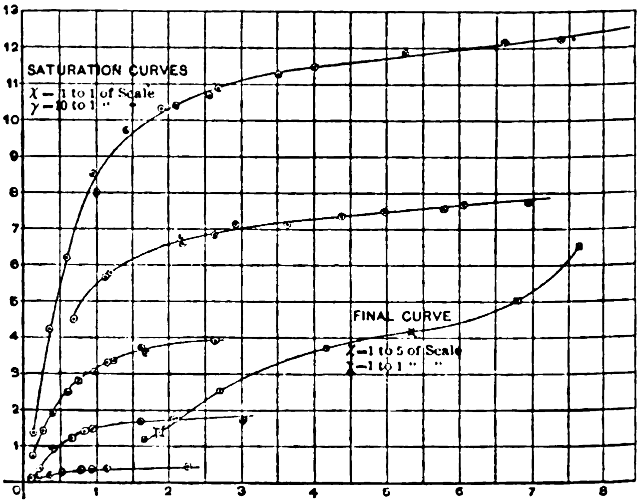

Fig. 5.

Fig. 3 shows more fully the connections with galvanometer at time of reversal. Fig. 4 is a larger view of key for closing induced circuit.

Digitized by Google

When the experiment was begun, I intended also to use for the smallest two cores a set of smaller spools of No. 14 wire, with same number of turns as the larger, to see if a different "highest economical current" would be obtained. Also to make tests of magnets with one armature off, and also to test a magnet with differently prepared surfaces of contact between armature and core. These experiments were omitted for want of time. It will be seen that the method of reversals is that of Prof. Rowland.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

The annual general meeting of this Society was held on Thursday, Dec. 2, at the Institute of Civil Engineers, Prof. Hughes, F.R.S. (President of the Society) in the chair. The Secretary having read the annual report, which showed that the Society was in a flourishing condition financially, and continued to increase in numbers and importance, votes of thanks were passed to the honorary officers of the Society both at home and abroad, to the Institute of Civil Engineers for their continued hospitality, to the donors of books for the library, and to others. The election of officers for the ensuing twelve months was then proceeded with, the results of which we were enabled to announce last week. During the scrutiny of the votes the discussion on Mr. Swinburne's paper took place, but as we are not able to complete this paper in the present issue we must reserve the remarks of the speakers.

The President then called upon Prof. Forbes, who had very kindly undertaken to fill up the remainder of the evening by speaking on "Some Magnetic Problems."

Prof. Forbes said that he had some hesitation in bringing these notes before the Society, because they mainly consisted of ideas suggested from theoretical considerations, and he had not as yet undertaken their experimental verification. He, however, had consented to occupy their attention that evening with this subject, in the hope that others who had more time or greater facilities than he himself possessed at the moment might be induced to put these ideas to the test. It has no doubt suggested itself to many people to inquire whether the labours of Œrsted, Faraday, Ampère, and Sturgeon have really extended over the whole field of electro-magnetic phenomena. Now, there is certainly one direction in which these phenomena have not been fully developed by experiment, and all the suggestions which he was about to make were founded upon this one idea—the idea of *a magnetic current.* If we have a long iron wire with a coil at the end, then when we pass a current through the coil the wire will be magnetised throughout its length. During the rearrangement of the molecules which ensues while the magnetisation is proceeding along the wire we have what may be called a magnetic current. The question then arises, what are the distinctive properties of this magnetic current? Some of these properties are already well known to many of those present. Suppose that we have an iron ring, wound with a coil of insulated wire continuously in the same direction. Then at the moment that an electric current either commences, is reversed, or ceases in the wire, we know that an E.M.F. is created along certain lines of induction, passing through the axis of the ring, and returning outside. If a conductor occupy any part of this space a current will be set up in it, but if there be no conductor present a strain is set up in the insulating medium. But if a charged body be present in a space where such a strain exists, then, if negatively charged, it will tend to move in the direction in which this strain is acting. Consequently a charged body placed at the centre of our ring should experience a force acting upon it at the moment of any change in the current through the coil. This is the first experiment which it is desirable to undertake. The effect would, however, be very small. He (Prof. Forbes) had calculated that in a particular wire, at a distance of two metres along an iron wire measured from the position of the inducing coil, the induction was only ·0001 of its value at the coil itself. Of course the conditions of the experiment which he had suggested were not exactly of the same character. He proposed the following method as likely to give measurable results:—Let a cylinder ring be wound all over with copper wire continuously in the same direction, like a Gramme ring, and placed with its axis horizontal. Within this cylinder the charged body would be suspended by a silk fibre, and would consist of a pair of concentric and separately insulated metallic segments, which could be charged like a Leyden jar, one pair being positive and the other negative. Then on magnetising or reversing the magnetisation of the ring by means of the current in the coil, a deflection should take place, and could be rendered visible by a light mirror in the usual way. Such an instrument would at once find an application in the measurement of the work done by an alternating current—a measurement which, as many of those present would know, involved difficulties of the most serious character. In fact, at the present time the employment of the calorimeter was really the only trustworthy method at their disposal. At the same time, the measurement of the work done by such currents was daily becoming more and more important, owing to the extended use of secondary generators. It is perfectly easy to measure separately the E.M.F. and the current, but what we want to know is the value of these two factors *at the same instant of time.* Our instruments tell us the mean alternating values, but the periods of maximum and minimum of the E.M.F. and current respectively do not correspond. Suppose, however, we had such an instrument as has been suggested, then we may send the alternating current through the coils of the Gramme ring, and at the same time we may connect the terminals of the circuit, where the work which we wish to measure is being done, to the segments which have to be charged; consequently, the segments will at every instant be electrified to the potential which we wish to measure, and the deflection of the discs will then be proportional to (or some function of) the product of this potential *and of the magnetisation of the ring by the current in the coils.* This arrangement does not, therefore (without some further modification), give us the quantity which we seek, but it gives the product of the potential into the differential of the current in respect to its period, because it is to this that the intensity of the *magnetic* current is proportional. Therefore, in order to adapt such an instrument to actual work it would be necessary to provide an additional pair of coils, wound upon one core, through one of which the primary current to be measured would be sent while the secondary induced current would then be passed through the coil of the instrument itself, and the phase of the magnetic current would thus be restored to synchronism with that of the first electrical current. This is only an introduction to the subject of magnetic currents, but he (Prof. Forbes) had no doubt that upon studying the matter for themselves they will discover an almost complete analogy between a magnetic current and a charged electrified body on the one hand, and an electric current and a magnetic pole on the other. Imagine, now, two parallel iron wires; let us inquire whether, when they are each traversed by magnetic currents, there would be any attraction or repulsion between them. It will be found that the analogy of electric currents holds good completely. If the currents are in the same direction we have attraction, if in opposite directions repulsion. Without going very fully into this, I think you will be able to see that this is right from the following illustration:—We have already seen that a charged body is attracted towards the axis of an iron ring through which a magnet current is passing. It therefore follows that the ring tends equally to move towards an electric field in its neighbourhood, parallel to the lines of E.M.F. Now, what does that lead us to? Suppose we have two rings placed one above the other. Each of these will, we know, create an E.M.F. in its neighbourhood when traversed by a magnetic current. Hence, if both are traversed by similar currents they tend to approach one another. And it is of course equally easy to show that if the current in one of them is reversed a repulsion is set up. If, now, we extend the size of the rings indefinitely, we can at once apply the same principles to the case of two parallel wires. Let us consider the question a little further. The attraction which exists between the two wires conveying similar magnetic currents must represent a certain amount of energy, and if work is done it must clearly be at the expense of the magnetic current itself; or, in other words, the approval of one magnetic current towards another induces a counter E.M.F. tending to diminish the strength of the magnetic currents. We may say, if you like, that a magneto-motive force is created which tends to set up a magnetic current in the opposite direction. This leads me to the fact that if I have a magnetic current travelling through one wire and approaching a second iron wire, it induces in that wire a magnetic current opposite in direction to the inducing current—one more analogy with the laws of electric currents. I need not go on and complete this by pointing out that a secession of one wire from the other will create a magnetic current in the same direction, or that the sudden making and breaking of the current in one wire without approach will suffice to create a current in the opposite direction in the second. Prof. Forbes concluded his remarks by again expressing a hope that the experimental study of the subject would be undertaken by some member of the Society.

Mr. Swinburne asked for some further explanation as to the action of Prof. Forbes' proposed instrument.

Mr. Biggs referred to the necessity for recognising electric and magnetic phenomena as having a common basis.

Mr. Preece agreed with Mr. Biggs' views as to the desirability of ceasing to draw a hard and fast line between electric and magnetic phenomena.

Mr. Snell described the use of Mr. Blakesley's method of determining the coefficient of self-induction.

Mr. Gisbert Kapp sketched on the blackboard an illustration of a simple hydraulic analogy.

Prof. AYRTON mentioned a remarkable experiment which he had in progress, by which the absolute velocity of the earth in space might be determined.

We regret that the extreme pressure on our space still compels us to hold over Mr. Swinburne's paper on "Secondary Battery Experiments."

MOTORS FOR ELECTRIC LIGHTING.

By the courtesy of the Secretary of the Society of Arts we have been favoured with an advanced proof of the following:—

The Council of the Society of Arts are prepared to award TWO GOLD MEDALS and FOUR SILVER MEDALS for prime motors suitable for electric light installations.

The medals will be awarded on the results of practical tests, the conditions for which are as follows:—

1. The motors will be divided into two classes, A and B. One gold and two silver medals will be awarded in each class.

(A.) MOTORS IN WHICH THE WORKING AGENT IS ALSO PRODUCED.

Steam.—Ordinary portable or semi-portable non-condensing engines.
Ordinary portable or semi-portable condensing engines.

Gas.—Coal gas or water gas with producer.
Petroleum vapour.
Liquid petroleum.

(B.) MOTORS TO WHICH THE WORKING AGENT MUST BE SUPPLIED.

Steam.—Detached engines, non-condensing, without boilers.
Detached engines, condensing, without boilers.

Gas.—Engines worked by illuminating or other gas.
Engines worked by raw gas without producers.

Hydraulic.—Water motors.

2. Each class will be subdivided into two groups—those declared to develop not more than 10 horse-power, and those which will develop more than 10 horse-power and less than 20 horse-power.

[The horse-power herein mentioned is equivalent to 33,000lb. raised one foot high in one minute, as measured on the brake]

3. The entrance fee will be £2. 10s. per horse-power, to be paid on entry.

4. No competition will be held unless ten motors at least are entered.

5. In case of no competition being held, the entrance fee will be returned.

6. The Council reserve the right of refusing any entry.

7. All engines and boilers must be fitted up in accordance with the Regulations of the Royal Agricultural Society, viz.:—

a. All boilers must be fitted with a steam pressure gauge. Before any engine can be worked the pressure gauge must be verified by the judges.

b. There is no restriction as to the construction of steam engines or boilers, but the judges must be satisfied that the bursting strength of the engine or boiler is at least four times its working pressure, and that a hydraulic test of one-and-a-half times the working pressure has been satisfactorily applied.

c. Each exhibitor must declare the greatest pressure at which he proposes to work his boiler or engine.

d. No old boilers, that is boilers that have manifestly been at work for a considerable time, will be admitted without special thorough examination and a certificate of safety from the judges.

e. Each boiler, of whatever form or size, must be provided with the following mountings:—

Two Safety Valves, each of sufficient size, to let off all the steam the boiler can generate, without allowing the pressure to rise 10 per cent. above the pressure to which the valve is set.

Two Sets of Gauges for ascertaining the water level.

One Steam Pressure Gauge, which must be tested and verified by the judges before the boiler can be used.

A Half-inch Cock, terminating in a half-inch male gas thread, for the purpose of receiving a testing pump.

One Check Feed Valve, immediately attached to the boiler, in addition to the ordinary pump valves, whenever the feed is introduced below the lowest safe water-level, or where there is a length of feed pipe between the engine and boiler.

f. Exhibitors must be provided with all the appliances necessary for taking the working parts of the machinery to pieces, for examination, should the judges require it.

g. Shafting, belts, gearing, high speed machinery, and any other exhibits likely to prove dangerous, shall be securely fenced and protected to the satisfaction of the judges, but such approval shall not relieve the exhibitor from his own liability.

8. The points of merit considered of the greatest importance are—

a Regularity of speed as to revolutions per minute under varying loads.
b. Regularity of speed during the various parts of one revolution.
c. Power of automatically varying speed to suit arc lights.
d. Noiselessness.
e. First cost.
f. Cost of running.
g. Cost of maintenance.

9. The tests will be carried out under the direction of three judges appointed by the Council of the Society of Arts, who will report to the Council, and will confer with them on the awards.

10. The Council will publish the awards in the *Journal* of the Society of Arts. They reserve the right of publishing descriptions of any of the motors, and the competitors must afford every facility for this purpose.

11. The competitors must take upon themselves, in exoneration of the Society, all claims in respect of damage (if any) resulting from the testings, and must renounce all claims for compensation for any injuries, real or imaginary, that they may incur from alleged or actual imperfection in the testings, or from any statement in the report or description published.

12. The competition will take place in London about May or June next. Entries must be sent in by the 28th February, 1887.

13. All costs of fitting up and working the motors must be borne by the exhibitor. The Society will provide the brakes, indicators, and apparatus, electrical and other, necessary for making the tests.

14. The Council reserve the right of withholding any or all the medals.

GLOW LAMPS, THEIR USE AND MANUFACTURE.*

BY MAJOR-GENERAL C. E. WEBBER, R.E., C.B.

(Continued fom page 113.)

In a good glow lamp, inseparable from uniformity of resistance are uniformity of surface and incandesence. Uniformity of resistance when hot means that each lamp will (so to speak) consume the same amount of current, and this can only be secured by electrical measurement under the conditions of uniform electrical pressure. Uniformity of incandescence and surface means that lamps possessing these qualities give almost the same candle-power, and this can only be obtained in the manufacturing processes by visual measurement. To secure all three it is necessary to combine a means of visual and electrical measurement. The former is but approximate, the latter is as accurate as a Thompson's galvanometer can make it. In either case, however, when large numbers of filaments have to be standardised, neither measurement can be expected to produce greater accuracy than is essentially necessary for a good commercial lamp, and the fact is that while uniformity of E.M.F. is the condition which must not be departed from, no harm arises in practice if the current consumed and the candle-power are not absolutely uniform. Thus, the required resistance of each lamp is such a resistance as will, under the conditions of uniform E.M.F. or electrical pressure, give, with a small varying area of surface, such a candle-power as that to the eye all the lamps are alike when they are incandesced.

This required resistance is obtained in the following way by a process known in the electrical world as "flashing," a title which, I believe I am right in stating, owes its origin to Mr. Lane-Fox:—The baked filament is placed in these tongs and lowered into a glass chamber full of hydrocarbon gas. An electric current is passed through it, which raises it to a high temperature, and the carbon in the gas attaches itself to, or is deposited on, the heated surface. The use of this beautiful phenomenon is not essential, but is a very ready and simple means for rapidly increasing the size of the filament, and necessarily in consequence for reducing its electrical resistance. While this is being done the operator is being guided by the two means of measurement already mentioned, so as to know when he has reached the required standard, by reducing the resistance to that point, under a uniform electrical pressure (now generally expressed as "with a uniform voltage"), at which the state of incandescence is reached which yields light of the candle-power required in the lamps under manufacture. The process, as you see before you, is one which is most conveniently carried out intermittently and cautiously, as, inseparable from it, just as the thickness of the filament is increased, so the resistance diminishes, and more current is required to give the high temperature which attracts the carbon from the surrounding gas. The filaments having been thus standardised, they have to be mounted or attached to the metal conductors, which pass through the glass, and thus make their ends electrically in communication with the outer air.

An important condition of the result of any process of doing this must obviously be the obtaining of a good and perfect electrical contact or joint between the metal and the carbon. The absence of this would be fatal to the future of the lamp. Every inventor has laboured hard to secure this. The making of good joints between the ends of electric conductors has been, for the last thirty years, the subject of intense care to every engineer who deals with electricity. No wonder that its importance should be vital in the case of these two little connections, knowing that once sealed up in this bulb they cannot be got at again for repairs, and also knowing the intensity of the current to which they must be the path. In joining iron or copper wires to one another, telegraph engineers long ago knew the difference in the resistance of their lines due to the careful use of soldered joints, instead of leaving them what they call "dry." Various forms of joints have been devised so that the tensile connections between the wires and the surfaces in contact exposed to the deposition of solder should be sufficient to neutralise all resistance. The efficiency of such devices became more important when the joints for the purpose under consideration had to be designed, because of the necessity not only to neutralise resistance at these points in the circuit, but also to reduce it at this point in comparison to that of the carbon. Although this desideratum is ardently sought, in practice it is difficult to prevent heating at the joint when the current exceeds 1·4 of an ampere. Hence many very ingenious little contrivances, but all having the same object.

Next is the question of the solder to be used, and I believe that no one will dispute that Mr. Lane-Fox was the first to use the process of deposition of carbon by electrically heating the joint in a vessel containing an

* Paper read before the Society of Arts, Wednesday, December, 8, 1886.

Digitized by Google

hydrocarbon surrounding, so as to solder the metal and carbon surfaces to one another. The way in which this is effected is pretty much the same in execution everywhere. The wire mount of platinum wire, or other suitable metallic conductor, is placed in contact with the carbon filament or bridge, so that they are kept together by any suitable contrivance of their ends, and the joint is then flashed. As any further deposition of carbon on the filament itself would alter the standard effected in the previous stage of the process of carbonisation, it will not answer to allow any current to pass through it. This is prevented by any simple means of short circuiting the current, so that it shall only pass through the joint. In the process carried out before you, this is done by this apparatus, which holds the filament in this vessel, which contains hydrocarbon in a liquid instead of in the gaseous form you saw used for carbonisation in the previous stage. Practically, the chemical phenomena are identical in each case, and the result in this one is a perfectly homogeneous electrical joint, larger in section than the other portions of the path of the current, and therefore of ample strength and conductivity to prevent risk of any future wear and tear through high temperature and rough usage.

There is not much to be said about the platinum mount. There are small details in its construction, and the manner of preventing its two sides coming into contact, which vary little in design, and all have the common object. You now see this done by the introduction of the little glass bridge piece. The platinum which should be used, its homogeneity and physical conditions, are all objects of experiment and great care, too minute with which to trouble this audience.

The Bulb.

Having completed this important factor in the construction of a glow lamp, let us turn to the envelope, or bulb, which is destined to be the home of the burner, under conditions for supporting combustion opposite to those under which any other means of illumination will act. In the latter the presence of oxygen in due proportion to the supply of hydrocarbon and other light-yielding gases is vital to its usefulness. In the former the presence of oxygen within the bulb and its contact with the carbon bridge is rapid death, instead of the slow decay, ending in extinction, which is the best that as yet can be expected from the glow lamp. Imperfect though it may be, it is, however, very good, and not likely to be superseded.

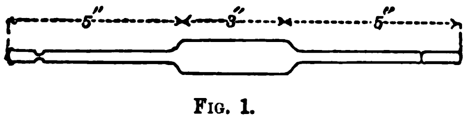

Fig. 1.

This little glass vessel has also its stages of manufacture, as you will see by the performance in your presence, the power of demonstrating which, together with the processes previously shown, I owe to the permission of the Board of the Anglo-American Brush Electric Light Corporation, whose factory and offices are situated on the Surrey side of the Thames, just over against Charing-cross. You see that a glass tube of about three-quarters of an inch interior diameter is the foundation. The first stage you see is to produce an object like this (Fig 1, previous col.), by drawing out the glass into a small tube of about five inches long, at each end of a section of the original tube about three inches long. Next the small tube is slightly contracted at (A), when the thick part is heated and blown to this shape :—

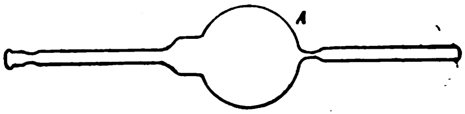

Fig. 2.

Under a second heating, with the object of completing the form of the bulb, it is brought to the following form (Fig. 3, below).

A Y is then cut off, and another tube of uniform section joined on in its place. This passage is afterwards used for exhausting. The bulb is now ready for the introduction of the filament, which has been prepared and mounted in the way you have seen. Z is warmed, the end taken off, and it is pressed into an elliptical shape. The filament is introduced, and under the influence of heat the glass is pressed around the platinum leads, and the little loops at their ends only are left projecting. The lamp is now ready for the last part of the manufacturing stage, in which a vacuum within the bulb is produced.

The last stage, namely, the exhaustion, is probably that upon which the life of the lamp most largely depends. This process, exemplified by the action of the mercury pump which you see here, is apparently a very simple one, and would be so were it not that there are several small impediments to success which, when one comes to demanding a vacuum of one millionth of an atmosphere, are very serious difficulties. In the first place, great attention must be paid to the construction of every part of the pump, for, with valves or taps of the ordinary kind, inevitable failure and waste of labour would ensue by leakage when the stage of high vacuum is being approached. I will avoid going into any description of the merits of the various forms of mercurial air pumps, because Prof.

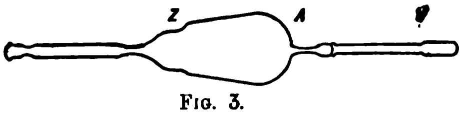

Fig. 3.

Silvanus Thompson will before long read a paper on that subject before this society, so I will pass on to some of the conditions of their use for exhausting glow lamps. It was found that the attempt to obtain such a vacuum as is required in the industry I have ventured to bring to your

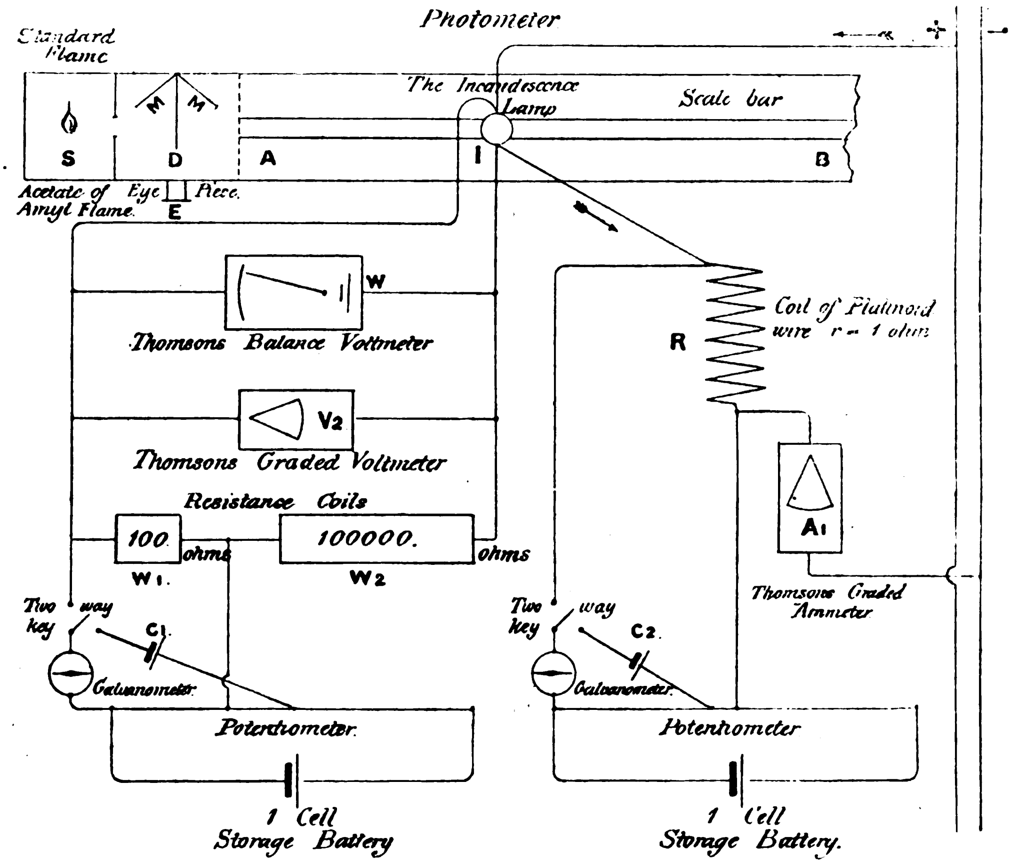

Fig. 4.

Digitized by Google

notice to-night has to encounter the presence of moisture in the air, and the presence of air in the glass, in the platinum, and in the carbon. Besides, the process of exhaustion is the only vehicle for ridding the filament of what are called the occluded gases. A part of the moisture can be, and is, removed by absorbent substances placed inside the pumps, but alterations of temperature in the glass and in the filament, brought about by several means, which I cannot show here, are alone found to be really effective, and this application of heat to expel the moisture and air from the parts of the pump open to the lamp must be continued, with exhaustion, at certain stages of the operation, until by a suitable test it was found that the requisite degree of vacuum has been reached.

The best vacuum test is probably that which is made electrically. This is carried out with an induction coil of very high tension, and the test consists in observing when the sparks between two poles of platinum, placed in a part of the pump which shares the vacuum with the lamp under treatment, travels outside the glass instead of inside. The process of exhaustion in the early days of glow lamp making occupied three or four hours; now it has, by better appliances, been reduced in time to a little more than half-an-hour. The number of lamps turned out in a factory is determined by the number of lamps on each pump, generally three or four, and the number of pumps. Allowing ten removes a day, and twenty-five pumps, each having four lamps, a manufactory could turn out 1,000 lamps a day. The lamps are next tested and classified for candle-power and voltage, and marked accordingly; formerly 50 per cent. failed to give the standard of efficiency in those respects, now all are up to the mark within 10 per cent. The electrical efficiency of lamps is measured by the watts expended per candle-power. As is well known, economy in this direction effects a saving for a given amount of light required on an installation of electric lighting, in power converted into electricity, and in the size of the conductors which convey it to the lamps. Most makers' lamps vary between 3 and 5 watts per candle-power, when the lamps are new, under the conditions of voltage which gives the longest life. Those are alleged to be as follow:—Edison, 5 watts; Swan-Edison between 3·5 and 4 watts; Victoria, 3·5 watts; Woodhouse-Rawson, 3·0 watts.

The scientific man does not require to be told what are the tests to which he should subject glow lamps to prove their efficiency. At the Crystal Palace Exhibition, at Vienna, at the Health Exhibition, and at Philadelphia, very exhaustive tests were applied to the lamps of several well-known makers; but at the best all these have proved unsatisfactory, because the makers themselves were not likely to contribute their average lamp, and in some cases either declined to contribute at all or repudiated the results after they were published. The tests which require apparatus not usually outside a laboratory are those which observe the E.M.F., the current, the resistance, and the watts per candle-power. There are various arrangements for testing candle-power. I am indebted to Dr. Fleming for that which is shown on the diagram (Fig. 4, page 131).

The arrangement is a very special one for securing an accurate E.M.F. in the lamp in process of testing. The disc D of a photometer is fixed, instead of, as is usual, being left free to slide. The standard flame at S is a lamp of burning pear-oil, or acetate of amyl, with a flame of regulated height. The lamp I to be tested is placed on a carrier which slides along the scale bar A B. First, to test the current. The current which feeds the lamps passes along the mains plus and minus, *viâ* the minus through a Thompson's graded ammeter and a platinoid resistance, R, to one terminal of the lamp. The difference of potential between the termini of the coil is compared with the E.M.F. of a standard Clarke's cell, C_2, on a potentiometer. This latter is a perfect check on the accuracy of the ammeter. Second, to test the working E.M.F. at the termini of the lamp. Similarly this is made with a Thompson's balance voltmeter, W, as well as a Thompson's grade voltmeter, V_2, checked by measuring the difference of potential at the extremities of a 100 ohm coil W_1, in series with a 10,000 ohms coil W_2. The voltmeters themselves are placed between the terminals of the lamp, but by means of the resistances the potentiometer, with a Clarke's standard cell, is only compared with $\frac{1}{100}$ths C_1 of the E.M.F. of the lamp.

It will be understood that the standard cell in each is the ultimate check on the measuring instruments, provided the resistances are perfectly true, and if the latter do not agree with the former, they have to be re-calibrated. The need for standardising the measuring instuments used by electricians has been pressed home by Dr. Fleming to the conviction of every one concerned, but up till now little has been done beyond deliberation by a committee of the Society of Telegraph-Engineers and Electricians. At present we do not know that we all mean the same thing when we speak of some of these units of measurement.

(To be continued.)

PHYSICAL SOCIETY.—Dec. 11.

Prof. M'Leod, Vice-President, in the chair.

W. Natanson, Ed. Natanson, the Hon. R. Abercromby, Jul. Verteimer, and H. M. Elder were elected members of the society. The following papers were then read:—*On the Influence of Change of Condition from the Liquid to the Solid State on Vapour Pressure*, by Prof. W. Ramsay, Ph.D., and Sydney Young, D.Sc., read by Dr. Young. The authors refer to some experiments published in *Wiedemann's Annalen*, Vol. 28, p. 400, by W. Fischer, on the above subject, which show that the vapour pressure of ice and solid benzene are less than those of water and liquid benzene at the same temperatures. By using the formula $p=a+bt+ct^2$ to express the relation between the pressure and temperature of saturated vapours, Fischer arrives at the absurd result that the vapour pressure of liquid benzene is not identical with that of solid benzene at melting point. If the above formula be replaced by log $p=a+b\dot{}a^t$ it is shown that the anomaly disappears. The authors have measured the vapour pressures of solid and liquid benzene by the dynamical method, and obtain results agreeing closely with those of Fischer determined statically. They also calculate the vapour pressure of solid benzene from that of the liquid by using the formula

$$P_{t-1}=P_t-(P'_t-P'_{t-1})\left(\frac{V_{t-\frac{1}{2}}+F_{t-\frac{1}{2}}}{V_{t-\frac{1}{2}}}\right)$$

where P_t and P'_t are the vapour pressures of the solid and liquid at temperature t, $V_{t-\frac{1}{2}}$ = heat of vaporisation of liquid and $F_{t-\frac{1}{2}}$ = heat of fusion of solid at temperature $t-\frac{1}{2}$. The numbers so obtained are in accordance with those determined experimentally.

On the Nature of Liquids as Shown by the Thermal Properties of Stable and Dissociable Bodies, by the same authors, read by Prof. Ramsay. From experiments on the vapour density and heat of vaporisation of stable and dissociable bodies, the authors arrive at two important results. (1) That for stable bodies, such as alcohol and ether, the density of their saturated vapours increases with rise of temperature, whereas for bodies such as acetic acid and nitric peroxide the vapour density attains a minimum at certain temperatures, and increases with either rise or fall of temperature. (2) The heat of vaporisation of alcohol decreases with rise of temperature; but that of acetic acid attains a maximum at about 110deg. C., and decreases with rise or fall of temperature. From these results the authors seek to prove that the difference between stable liquids and their vapours consists in the relative proximity of the molecules, this proximity being greater in liquids than gases, and that the molecules of stable liquids are not more complex than those of their gases.—Prof. Pickering dissented from this view, and thought that the molecules of liquids are aggregations or compounds of those of the gases.—In answer to inquiries by the authors, Mr. Lewis Wright said bodies which rotate the plane of polarisation of light when in the liquid state also rotate it in a proportionate degree when gaseous, and Captain Abney remarked that stable liquids and their vapours give similar absorption spectra, whereas those of dissociable bodies differ considerably. Both these facts seem to support the view put forward by the authors.

An Account of Cauchy's Theory of Reflection and Refraction of Light. By Mr. James Walker, M.A. This paper is intended as a statement of the work previously done in the subject, and gives references to the original papers and "reproductions," &c., which will be of great value to persons studying this important branch of the "Theory of Optics."

Mr. Shelford Bidwell exhibited and described a voltaic cell in which the electrolyte is dry peroxide of lead. It consists of carefully dried peroxide placed between plates of lead and sodium, and gives a comparatively strong current, which passes from the sodium to the lead within the cell.

LEGAL INTELLIGENCE.

The Direct Spanish Telegraph Company (Limited) *ats* Bannatyne.

This was a petition heard before Mr. Justice Kay, in the Chancery Division of the High Court of Justice, on Saturday last, for the sanction of the Court to allow the company to reduce its capital in accordance with a special resolution passed on the 30th of September last, and confirmed at a subsequent extraordinary meeting held on the 19th of October. The resolution was as follows:—"That in consequence of the abandonment of the Company's original cable, the capital of the company be reduced from £190,000 (at present represented by 6,000 preference shares of £10 each, all issued and fully paid up, and 13,000 ordinary shares of £10 each, whereof 12,931 are issued and have £9 per share paid up, and 69 are unissued) to £95,000, and that such reduction be effected by writing off £5 per share from the amount credited as paid up on each issued share, and £5 per share from the nominal amount of each unissued share, the amount so written off the issued shares being capital not represented by available assets."

Readers of *The Electrician* will remember that in consequence of the passing of this resolution, Mr. Neil Bannatyne, who was at one time Chairman of the Company, and who attended both the meetings in question, and in company with one or two others recorded his vote against the resolution, applied for an injunction on behalf of himself and the other holders of preference shares, to restrain the Company, Sir James Anderson (its present Chairman), and the other Directors of the Company, from giving effect to that resolution.

The case was heard before Vice-Chancellor Bacon, and was fully reported in *The Electrician* of November 5th. The Vice-Chancellor having granted the injunction asked, an appeal was at once lodged, and the case was again heard before Lords Justices Cotton and Fry, and reported in our issue of the 12th and the 26th of November last. The result of that appeal was that the injunction granted by the Vice-Chancellor was disallowed, and the action was dismissed with costs. Hence the present application to Mr. Justice Kay to grant the confirmation order.

Mr. Rigby, Q.C., who appeared for the company at the previous trials, again attended in support of the application, which on this occasion was unopposed. The learned counsel at considerable length entered into the history of the circumstances which led to the necessity of the proposed reduction of the capital, and practically recapitulated his former arguments. He said that the application was perfectly *bonâ fide*

Digitized by Google

and within the Act, because having lost £95,000, if the shareholders thought it in their interest, it was perfectly right to reduce the capital by that amount. It was the only possible way of reducing it, for there was no suggestion in the Act that they might reduce one part of the capital without making a corresponding reduction of the other. All the capital was part of the original capital, and whatever reduction took place with regard to one part must necessarily apply to the other. He could imagine that if this had been a case in which it could be shown that the proposed reduction was to be made at the expense of any section of the shareholders, there might be some objection to the granting of the petition. But it was not so. Moreover, the majority of the shareholders, both ordinary and preference, had, believing it to be for their interest, voted in favour of the resolution. On the whole case, therefore, he submitted that the Company brought itself within the terms of the Act, and that this was a case in which the Court might well exercise its discretion in granting the confirmation order. If his lordship took this view and granted the application, it was asked that the Company might have liberty to revert to their old form of title, and omit the words "and reduced" which had been used since the presentation of the petition. This could all the more easily be done since it was not a matter in which the creditors could be affected.

Mr. Justice KAY reserved judgment.

Yesterday morning Mr. Justice Kay delivered the following

JUDGMENT.

Mr. Justice KAY: The Court is asked to confirm a resolution for reduction of the capital of this Company.

The case is one in which creditors are not affected, because no capital is to be returned, nor is the liability of the shareholders to be diminished; but the Company, having sustained serious loss by the destruction of one of their submarine telegraph cables, desire to write off a portion of the paid-up capital on which they pay dividends, and thus to enable themselves to release part of a reserve fund which they have been forming, and which they now propose to apply in payment of the arrears due on the preference shares. The shares are preference shares of £10 each, fully paid up, and ordinary shares of the same nominal amount, on which only £9 has been paid. Dividends are paid not on the nominal amount, but upon the amount paid up on each.

In the Articles is a provision that the Company should have power by special resolution to reduce their capital or alter the amount and denomination of their shares. The preference shareholders having taken shares subject to this provision, it has been held in a litigation commenced by some of them to restrain the present proceeding for reduction, that it would not be contrary to the contract with them to do so—that they cannot maintain that there was an absolute bargain to divide among them an annuity equal to the total amount of the dividends on their paid-up capital, but that the contract was to pay to each £10 per cent. on such capital, subject to the liability that the capital might be reduced by proper proceedings for that purpose under the terms of the Articles.

The power given to the Court by Section 11 of the Companies Act, 1867, to confirm a resolution to reduce capital is a discretionary power—that is to say, the Court must exercise it, by confirming with or without conditions, or declining to confirm on a full consideration of all the circumstances. One matter to be taken into account is whether the proposed scheme would work injustice between the different classes of shareholders.

I agree that if the Court should think that would be the effect it would not be the function of the Court to impose conditions which would amount to an alteration of the scheme, but the proper course to take if such an alteration should be requisite would be simply to refuse to confirm the resolution, leaving it to the Company to prepare a new scheme if they thought fit.

Several cases of hardship and inequality as between shareholders were suggested. Suppose there were preference shareholders of £5 shares and ordinary shareholders of £10, all fully paid up, and the proposal was to write £5 off each share, that would totally extinguish the preference shares for the benefit of the ordinary shareholders.

If all the shares were £10 shares, but the preference were £5 paid and the ordinary £10, writing off £5 in that case would have the same effect until the rest of the capital were called up on the preference shares.

Again, if the proposal were to return capital to the shareholders, cases might arise involving questions as to whether the return should be in proportion to the nominal amount, or to the amount actually paid on each share. A return of capital in the winding up of a company may perhaps be hardly analogous, because then the liability for further calls is then taken away by dissolving the company. But upon consideration I do not think that the proposed reduction in this case will be unjust as between the shareholders. It is intended to write off £5 per share of the amount actually paid both on the preference and ordinary shares. As dividends are paid only on the amount paid up per share, this will reduce the dividend payable to the preference shareholders by a larger amount than that payable to the ordinary shareholders. That is to say, supposing the profits to be sufficient to pay 10 per cent. on all the capital paid up, the preference shareholder would be entitled to receive £1 per share, and the ordinary shareholder only 18s. By the reduction the preference shareholder would be deprived of 10s, leaving him 10s. per share, and the ordinary shareholder of 10s., leaving him 8s.

But unless an equal dividend had been paid on the preference and ordinary shares, which I understand has not been done in this case, the reduction may increase the chance of the ordinary shareholders receiving a dividend, or increase the amount per share which they may receive. The preference shareholders, no doubt, are induced to consent by the payment which is to be made of the arrears of their dividends. But this also will be an advantage to the ordinary shareholders, because in this Company I understand they are not entitled to anything until the arrears on the preference shares have been provided for.

The publicity which has been given to the matter by the litigation to which I have referred renders it unnecessary to continue the words "and reduced" as part of the name of the Company. There must be the usual advertisements in the *Gazette* and *Times* newspaper, and subject to this the Court confirms the resolution.

Mr. BEALE: The words "and reduced" are not to be put in.

Mr. Justice KAY: I have said so.

Mr. BEALE: I think the words of the Act confirm the reduction of capital. In this case is will not matter whichever way it is. Then will your Lordship approve of the amount for the advertisement. It is set out in paragraph 12 of the petition, and we ask the Court by the same order to approve that for the purposes of the Act of 1867 and 1877.

Mr. Justice KAY: It was stated to me that the shares were £9 paid up, but this states them as £4 paid up.

Mr. BEALE: That is after the reduction. £5 is wiped off.

Mr. Justice KAY: I should not understand the minute.

Mr. BEALE: The minute is to represent what the capital is after the reduction is confirmed by the Court.

Mr. Justice KAY: Which is the section of the Act.

Mr. BEALE: Section 15 of the Companies Act, 1867, and 4th section of the Act of 1877. The details were amplified by the 4th section of the Act of 1877. You were required to state a little more.

Mr. Justice KAY: Does this mean that the capital of the Company is reduced to £95,000?

Mr. BEALE: Yes.

Mr. Justice KAY: Then you should put in the words "as reduced"—that the capital of the fund as reduced is £95,000, in 19,000 shares of £5 each. Of the said shares 6,000 are preference shares, bearing a 10 per cent. preferential dividend, and all issued and fully paid up, 12,931 are ordinary shares issued and having £4 per share paid up, and the remaining 69 are ordinary shares remaining unissued.

Mr. BEALE: That is the detail required by the Act of 1877.

Mr. Justice KAY: But is that it?

Mr. BEALE: Yes, I have an affidavit verifying it.

Mr. Justice KAY: Then I will approve the amount as I altered it.

Mr. BEALE: If your lordship pleases—dispensing with the words "and reduced."

Edison and Swan United Electric Light Company v Woodhouse and Rawson.

This was an appeal of the defendants from the judgment of Mr. Justice Butt, for Mr. Justice North dated May 20th, 1886, which came on for hearing on Monday, before Lords Justices Cotton, Bowen, and Fry, in the Appeal Court.

Sir Horace Davey, Q.C., M.P., and Mr. McRory appeared for the appellants; the Attorney-General (Sir Richard Webster, Q.C., M.P.), Mr. Aston, Q.C., and Mr. Moulton, Q.C., representing the Company.

Sir HORACE DAVEY, in opening his case, explained that the part of the judgment complained of was so much of it as found for the plaintiffs, the Edison and Swan Company, on the ground of the patent having been infringed. The action was founded upon three patents—the Edison patent, which was the one now in question, and which was taken out on the 18th November, 1879, its number being 4,576; secondly, a patent originally taken out by a gentleman of the name of Swan, called the Swan patent; and, third, a patent taken out by a person named Gimingham, all the three patents being vested in the plaintiff companies, or some or one of them. The case as regarded Swan's and Gimingham's patents was abandoned by counsel in the course of the trial, and the only part of the case left, therefore, was that with regard to Edison's patent, the judgment providing for so much of the action as related to Swan and Gimingham's patents being dismissed with costs against the defendants. As to Edison's patent, the learned judge found that it was valid, and construed it in a particular way, and construing it in that particular way, it was not seriously disputed that the patent was infringed. The appellants from that judgment submitted to their lordships that the patent was not a good one, that it was not the proper subject matter for a patent. They said that the second claim, which was the one alleged to have been infringed, by giving it the construction which the learned judge put upon it, was too wide. If, on the other hand, the second claim was limited in a way which their lordships would appreciate, then they would say that there was no evidence of infringement. In fact, it was the old dilemma that so often arose in patent actions:—"If you construe a patent in such a way as to uphold it, then I do not infringe it; but if you construe it in such a way as to catch me in its meshes, then it is too large." Of course, when a patentee was endeavouring to uphold the validity of his patent, he was anxious to point out to the Court how extremely careful he had been to bring it within the limits of moderation; but, on the other hand, when he construed his patent for the purpose of catching an alleged infringer, he was anxious to show how large his sweep was, and how it included in its meshes the defendants in question. Having explained the difference between arc and incandescent lighting, the learned counsel proceeded to say that the scientific law relating to resistance might be expressed with sufficient accuracy by saying that the resistance, other things being equal, varied inversely to the sectional area of the medium or the burner, and directly to the length of the conductor—that was to say, the thinner they got their conductor the greater was the resistance, and the longer they got it the less was the resistance. That law was well known before the date of Edison's patent, which was not disputed. Having read Edison's final specification, the learned counsel said that the question which their lordships would really have to decide, assuming that

Digitized by Google

they took the same view of the construction of that specification as the learned judge did, was, what was a filament? The witnesses differed very much in their ideas as to what was a filament; but they were all agreed that a filament did indicate a certain thinness or smallness of sectional area, and the question was, what thinness or what sectional area would make a filament? All that Edison said was that he had discovered that a fine cotton thread, properly carbonised and placed in a sealed glass bulb, exhausted to one-millionth of an atmosphere, would offer a certain amount of resistance; and he went on to show the advantages of that burner or thread being coiled as a spiral, because they were able to get a longer length into the bulb, which therefore offered a greater resistance; and being thus coiled, the whole of it did not act as a radiating surface. He then drew the attention of the Court to the method of manufacture described by Edison, and went on to say that if the pith and marrow of the invention, to adopt the favourite expression of his friend, Mr. Aston, was the discovery that the reduction of the size of the sectional area of the burner in an incandescent lamp gave it increased illuminating power, then he maintained that was not what was described in Edison's patent. He maintained that was too vague, and not proper subject matter of a patent, but was merely telling the world that a certain advantage was gained by reducing the size of a particular part of a well-known machine. He said, in fact, that this question of a filament was merely one of degree, and although Mr. Edison might have made a meritorious discovery, it was not one which constituted the subject matter of a patent.

The Court then adjourned.

On resuming his argument on Tuesday morning, Sir Horace Davey proceeded to read and comment upon the evidence of the witnesses given at the trial, and to draw the attention of the Court to the invention of King and Roberts respectively in 1845 and 1852, and said that the reason why the incandescent lamps of those inventors were not successful was that they could not get a sufficiently good vacuum. But by the invention of Sprengel's pump a better vacuum was obtained, and rendered possible the use of carbon lamps. It was not known that those lamps attained a commercial success, but it must be remembered, as had been stated by one of the witnesses at the trial, that incandescent lamps went out of favour chiefly owing to the fact of their not having been able to obtain a perfect vacuum, and to the great expense attending them, because at the time of day the process of generating a current of electricity by means of dynamos was not known. What had made electric lighting a great success was really the invention of the dynamo. In the year 1874 or 1875 Sprengel's pump was brought out, and became a part of the scientific knowledge of the world, and gave an impetus to the subject of incandescent lighting; and following upon that, in the year 1878, the attention of scientific men was directed to a patent (3,988) by Mr. Lane-Fox, which was extremely important, as it showed that it was part of the common stock of knowledge that, in order to obtain a successful lamp, they must reduce the sectional area of the burner. The great merit of Mr. Edison's patent was there explicitly stated. He then referred to three other patents taken out by Mr. Lane-Fox, and said that on reading the three specifications relating thereto they had an incandescent lamp, consisting of a glass bulb or receiver, and a bridge of any suitable material supported between two platinum wires, and they had also, on the face of the specifications, evidence that the patentee was aware that in order to make a useful lamp it was expedient to get a high resistance, and that he was also aware of the law by which that resistance was to be obtained. Therefore, he ventured to submit to their lordships that in all essential particulars Lane-Fox's invention included the lamp that Edison described. If Edison's lamp was a patent for a burner made in a particular way, then he did not say it was included, but if it was for all lamps in which the sectional area was small, then he submitted it was included. Again, before the date of Mr. Edison's patent, Mr. Swan, who afterwards made an offensive and defensive alliance with Mr. Edison, had directed his attention to the same subject, and had delivered three lectures—two at Newcastle on the 19th Dec., 1878, and the 4th Feb., 1879, and a third at Gateshead on the 13th March, 1879—in which he described a lamp (which was burned at the lectures) which contained the essential elements of Mr. Edison's patent, except that the carbon burner was what was described as a pencil of carbon, or as some of the witnesses termed it, a rod of carbon. There was no actual evidence as to the mode in which that was obtained, but the carbon burner was said to be by Sir Frederick Bramwell and Dr. Hopkinson, about $\frac{1}{25}$th of an inch in diameter, and it was said that that was not a carbon filament after the manner of Edison's patent; first, because the sectional area was comparatively speaking large, and second, that according to the witnesses the carbon pencil, from its appearance, appeared to have been cut and shaped out of a block of carbon, whereas it was said it was an essential feature of Edison's filament that it should be shaped before it was carbonised. Sir Frederick Bramwell (and, he believed, Sir Richard Webster, in his opening address, did) attached great importance to that as a feature of Mr. Edison's filament—that it was formed into a filament before it was carbonised, instead of being cut out of a material already existing in the form of carbon. In the Court below great stress was laid upon that point. If his learned friends were right in their construction of the patent, there was nothing which confined the claim to be carbon filaments which had been made into filaments before being carbonised, nor was there any particular mode pointed out in which the carbonisation was to take place. It was merely said to be in a closed vessel, which was well known before the date of Edison's patent. Edison did not confine himself to any particular shape of the filament, except as regarded the spiral, which was a particular application of it. They had, therefore, only to deal with the thinness or thickness and size of the burner. He had already anticipated to a certain extent what his point was. He asked the question the previous day, What was a filament? He then read the various definitions of the word given in the best known English and French dictionaries, as well as Rodgers's "Thesaurus," and proceeded to say that the opposite side maintained that a filament included the idea of flexibility and resilience. They also said it involved the idea of sectional area, What amount of sectional area he asked? It was surely the duty of the patentee to tell the world what it was that he claimed the monopoly of. If the description or the claim was so vague that people could not tell whether they were within or without that claim, he submitted that according to well known principles of patent law (which he intended to illustrate by reference to a few authorities) the patent was bad and invalid. It seemed to him that this was the material and crucial part of the case—what was a filament? His contention, as their lordships would by this time understand, was that it was a mere question of degree. To illustrate his case he would refer to King's invention again. King described a lamp with the best known vacuum that he had at the time, with a carbon burner or pencil in a glass receiver from which the air was exhausted. When Sprengel's pump was invented he had a right to use that instrument to get a better vacuum. He became acquainted with the law as stated by scientific men by which they could obtain a high resistance. Was he not at liberty to reduce the size of his burner to any extent that he pleased? Was a man at liberty if—Mr. Swan, he would suppose—in the course of his investigation he ascertained that if he reduced the size of his burner he would produce particular results—could a man go and forbid Mr. Swan, forbid Mr. King or Roberts, from reducing the size of his burner? If the whole patent was reduced to the substitution of a filament of a small sectional area for a small pencil or rod, he submitted that it was not proper subject matter of a patent. Having read the evidence elicited from Dr. Hopkinson in his examination, as well as that of Dr. Fleming, the learned counsel submitted that it went to show that it was entirely a matter of degree whether the burner was called a filament or not. If Edison had introduced the idea of flexibility and resistance into his definition of a filament there might have been something in the contention of his learned friends. But there was nothing of the kind spoken of. It was purely a matter of degree, which they could not define. Mr. Imray, who was also examined on the same point, gave similar testimony. He (Sir Horace Davey) would go further, and say they had proved that it was not a question capable of definition. Edison's specification gave no indication of size, except as regarded the putty wire to be formed into a spiral, and therefore it came to nothing more than this—a direction to adjust the size of the burner to the desired resistance, having regard to its length, of course, and the electromotive force, the patentee adding that, in his opinion, a high resistance would be found to give particular advantages. Now, if that was so, he submitted that that was nothing more than a statement of a well-known law, and a practical direction to persons to adjust the size of their burners to the required resistance, as King and Lane-Fox had previously announced in their publications. What, then, was the law on the subject? He would refer their lordships to a case where it was decided that a patent could not be obtained for a particular mode of using or a particular modification of an existing and well-known machine. The learned counsel then proceeded to argue that the claim of Edison was analogous to the case of Kay *v.* Marshall (8 House of Lords Reports), by which it was established by Lord Lyndhurst that a patent could not be obtained for modifying the dimensions in a part of a well known machine. In the face of that decision could Mr. Swan have been told, "You shall not reduce the size of your burner?" Could they have told Mr. King, "You shall not reduce the sectional area of your burner?" He ventured to submit not. He had pointed out in reading the specification of Mr. Lane-Fox and of Mr. King, that they pointed out to the world that persons must adjust the size of the wire so as to obtain the amount of resistance which it was desired to obtain for a lamp, having regard to the amount of the electromotive force. It was quite true that no one ever described that as a filament; but he ventured to submit that Swan's lamp, King's lamp, and that of Lane-Fox, being well known, they could not; and further, it being known what the law of resistance was—that was to say, that in order to produce a successful lamp the resistance must be adjusted—they could not take out a patent in the face of the action Kay *v.* Marshall, and say "I will protect and have a monopoly of this machine with a particular sized burner and a particular sectional area." The learned counsel next cited Ralston *v.* Smith (reported in the House of Lords cases, page 223) in further proof of his contention, and went on to observe that there was nothing new in Edison's lamp in the second claim in regard to the mode in which it was worked. It was a lamp like Mr. Swan's or King's by which the light was produced by passing an electric current through wires sealed in a glass receiver; the maufacture was exactly the same in each, and the use which was made of the various parts of the combination which went to make up the lamp was precisely the same in each. What was the difference then? That Mr. Edison supposed himself to have discovered—which he (the speaker) would assume for the purpose of argument that he did discover—that a particular sized carbon burner would give a particular beneficial effect. That was no new process of manufacture. The principle on which the lamp acted and the light was obtained was in every respect the same. It was only a particular use—or rather, he ought to say, the most beneficial mode in which a well-known machine could be used. In other words, it was nothing more than this, that the patentee told Mr. Swan, for example, who had used these incandescent lamps before the date of Edison's patent, "You shall not be allowed to reduce the size of your burner, because I think that that reduction will give you particular beneficial results."

Lord Justice FRY: You say that it is only a new mode of using an old machine.

Sir HORACE DAVEY said that was his contention. The case of Paterson *v.* the Gas Light and Coke Company (2 Chancery Div. Reports, p. 812) was next referred to, and the learned counsel contended that, although there

Digitized by Google

was some distinction in that case, inasmuch as there was no alteration of the machinery but only in the way of working it, the reasons given by Lord Justice James, in deciding it, applied with equal force and cogency to the present case. He also quoted the decision of Lord Chelmsford in Harrison *v.* the Andertown Foundry (1 Appeal Cases, p. 581), and asked whether, having regard to the evidence before their lordships, it was possible to say that the second claim, interpreted as it had been by the Court below, did define and limit precisely that which was claimed to have been invented, and, therefore, patented? He was willing to rest his case upon that test. He now desired to call their lordships' attention to a part of the evidence which he thought went directly to the root of the matter, and that was this. Supposing his learned friends were right in saying that the great merit of Mr. Edison's invention was that his filament was shaped before it was carbonised. There was conclusive evidence to show that that was not new at the date of Mr. Edison's patent, and that a French gentleman named Sidot had written a paper, which was published in England, in which there was described a mode of carbonising filaments of thread and splints of wood and other things, and which went on to say that those threads and splints of wood, when carbonised, would be useful for electric lighting. Extracts from the paper in question having been read, Sir Horace Davey pointed out that his learned friends at the trial tried to get rid of that difficulty by saying that Sidot referred to arc lighting. But Sidot spoke, as their lordships would observe, of a piece of carbon becoming gradually incandescent. It might be that Sidot meant to include both kinds of electric lighting; but that was not the point. What he wished to insist on was this, that in Sidot's paper they had a description which might lead persons towards using carbonised thread, hemp, and splints of wood for the purpose of electric lighting. What was to prevent Mr. Swan, for instance, from carbonising a piece of thread or wood in the manner pointed out by Sidot, and substituting it for the carbon pencil in his lamps? Were they to deprive a man of the right of using in a machine which he had the right of using the best materials which were known at the time? And yet their lordships would see that this patent, in the sense in which the other side supported it, would prevent all the gentlemen whom he had named from making use of the various discoveries which were useful for the purposes of the machine which they already possessed. Commenting on Prof. Dewar's evidence as to experiments which he had made on Sidot's instructions to obtain the results claimed, the learned counsel ventured to describe it, as he had done in the Court below, as a signal example of trying how not to do it, because in cross-examination it was elicited from Prof. Dewar that he had disobeyed every one of Sidot's directions, and, consequently, had not obtained Sidot's results. Prof. Dewar did, as a matter of fact, everything which was necessary to make the experiments a failure. He then proceeded to read the evidence given in the lower Court upon the subject of the spiral, which Edison claimed not as a spiral in his lamp but as a claim *per se*, and submitted that it was a claim of something which was known before the date of Edison's patent, as was fully borne out by the patents of Van Choate and Pulvermacher taken out about the year 1878, the specifications of which were read at length. He submitted that those specifications were a description of a spiral of the size necessary to give the desired amount of resistance, and therefore included all sizes, consisting, it might be, of carbon, platinum, mica, asbestos, or any other combination, the mode described of making the spiral being identical with one of the methods described by Edison himself.

The Court then rose

On resuming on Wednesday morning, Sir Horace Davey proceeded to analyse the evidence of some of the chief witnesses at the trial, and concluded by reading the judgment of Mr. Justice Butt.

Mr. ASTON, Q.C., in the absence of the Attorney-General, opened the case for the respondents. He said that if there was one thing that he thought had been made more clear to their lordships than another, both from the reading of the judgment of the learned judge and from the address of Sir Horace Davey, it was that prior to the date of Edison's patent there was no good practical working incandescent lamp. It was very true that their lordships had had their attention called to various attempts that were made prior to the date of Edison's patent of 1879 by persons of great ingenuity and thoroughly acquainted with all the requirements of people who wanted electric lamps. There was a long list of them, from King down to Lane-Fox. The learned counsel then detailed the desiderata of an incandescent lamp, and said that down to the 10th of November, 1879, the chief problem how to use in an incandescent lamp a material whose molecules were of such a character, and which were so physically connected together as to allow them to have the necessary amplitude of vibration which would cause intense light, and yet, at the same time, would prevent the destruction which would follow from the particles being made to vibrate with that intensity, was unknown. It was no doubt known to King and others that carbon was a good material, and it was attempted to use it in a variety of forms. But in all those cases there seemed to have been something which everyone missed, which was a distinct essential, namely, something which would put it in such a condition that the disruption of the form of the carbon when used should be prevented. Referring to the discoveries of Mr. Lane-Fox, he went on to say that that gentleman, when he got as far as his discovery of the metallic wire, was on the threshold of Edison's invention. But he must call the attention of the Court to this important fact, that the filament of Edison's lamp was raised to a heat of something like 2,000 centigrade when the lamp was in full glow. There therefore took place, as might be imagined, an elongation of the filament itself, and a disturbance of the particles would have to be provided for. If they took the platinum wire recommended by Lane-Fox, they had the necessary expansion and contraction provided for, but there were other inconveniences attaching to the use of a metallic wire, which, as a matter of fact in the case of Lane-Fox's lamp, resulted in failure. The ultimate outcome of all that Lane-Fox had done, according to Sir Frederick Bramwell, was that he had constructed what was called his luminous bridge, which remained in the state of an attempt never carried into effect, as far as was known, and as to which their lordships had not a particle of evidence. They would bear in mind what Dr. Hopkinson said, that there must be in a filament resiliency and flexibility in order to provide against alternations of heat and shock, and he further said: "I do not know how that can be attained, unless the filaments are made as Edison tells you how to make them." So also the desiderata which were required up to the date of Edison's patent were not found in Swan's lamp, which he would show was an entire failure.

The Court then adjourned.

On resuming his argument on Thursday morning, Mr. ASTON referred to an account given by Mr. Swan himself, reported in the *Transactions* of the Newcastle-on-Tyne Chemical Society, and the observation he founded upon that was that Mr. Swan, who had come nearest of all persons to the discovery of Edison, had failed to see the cause of the want of practical utility in his lamp, or that he used a carbon-rod instead of a filament. It never occurred to him to say that he got disruption because he got his carbon in a wrong physical shape or form. It was when Edison applied the filament in a proper form that the incandescent lamp was for the first time an accomplished reality. He then pointed out that the dynamo machine and the Sprengel pump had been available for many years before the date of the patent. Having read the specifications of Van Choate, and extracts from M. Sidot's paper, the learned counsel ventured to submit to the Court that if Edison's specifications were construed by the light of the evidence, it would be found they were entitled to claim for a specific incandescent lamp having the elements constructed as described; and a combination with a filament not made with metal but of carbon, and put in an exhausted receiver through which sealed conducting wires were passed; and a claim to a specific spiral arranged in a specific manner like to nothing which had appeared before.

The ATTORNEY-GENERAL then took up the case and said that their lordships would find that it was conceded by the defendants' witnesses when he came to read certain passages of their evidence that the combination which Mr. Aston had just described was absolutely new. This was the case which he was going to prove out of the mouth of every witness who had been called in the case. He would not stop now to refer to Ralston *v.* Smith and Kay *v.* Marshall, as their lordships would find when he came to consider them, that they were cases of claims to make the subject matter of a patent the using of an old machine in a new way. There was a broad line of distinction, as Lord Esher in more than one case pointed out, between a new commercial article — meaning a new manufacture in the sense of being a concrete product — and a new mode of applying an old machine, or old ingredient. It was conceded by every witness that whereas prior to the date of the publication of the complete specification of Edison, incandescent lamps were absolute failures—were commercially unknown—from that time they were uniformly and universally a success. Their lordships were perfectly entitled to say to him "that will not help you to construe the specification, unless the specification admits the construction that you are contending for." But in view of the inference to be drawn from the evidence, he would ask their lordships to find that an admission was made and acceded to by Sir Horace Davey and Mr. Charles, and was amply well founded, that the specification contained perfectly sufficient instructions to enable a competent workman to make the incandescent lamp therein described, and that everything that had happened since had been an improvement on that incandescent lamp, and not a different lamp. What was the invention? It was this, that Mr. Edison, for the first time, found that they could rely upon carbon threads alone to have sufficient characteristics for the purpose of electric lighting. He found that for incandescent lighting they could rely upon the strength, the toughness, the resistance, the resilience (if it were material), the flexibility, and whatever was essential to make a successful electric light, that they could rely upon carbon alone in the shape of a thread, and made into a thread before it had been carbonised. It was impossible to overestimate the importance of that discovery, whether it were regarded from a scientific or commercial point of view. Up to that time the course of discovery had been leading people wrong for 20 or 30 years. It had been known for a considerable time that carbon would act as a conductor or illuminating medium in electric lighting, but it had never entered into the mind of anybody that they could rely for practical electric lighting upon a thing so thin and fragile (and yet having the properties which made it successful) as a carbon filament which, if it were taken out of the lamp, would break in one's hands, so exceedingly delicate was it in manufacture. The latest exponents, including Mr. Swan himself, had proceeded on lines which showed how little real knowledge they had, great as their knowledge was, and great as their experience had been, as to where the keynote of the whole secret lay. Knowing that carbon was a proper and useful conductor, as a medium through which the electricity could pass, and the light radiate, Swan was possessed with an idea that it was not strong enough, and, accordingly, having got a proper proportion of carbon in his conductor to pass the current, the strength of which could be measured to the greatest nicety, he proceeded to build up the strength of that conductor by non-conducting *media*. He took a stick of carbon—a thing rigid in itself—and tried to work it down to a sufficient small cross-section to get the proper resistance in the circuit. When they were approaching this argument they had simply to consider what was the previous knowledge of people on the subject. The whole of that knowledge might be divided into two classes—the knowledge of the people who, having got carbon in the shape of a powder or pulverised substance, built up a bridge in which carbon formed the conducting element, or of those who took a stick of carbon and endeavoured to work it down to something that would act effectively. Edison had in

Digitized by Google

his specification described that which was absolutely new, and in terms that no workman could mistake. It was an entirely different question whether the specification was sufficient to enable them to make the article, and whether the claim did or did not accurately describe what was the sort of combination to be protected. He was not there to say whether his clients could make as good a lamp as Messrs. Woodhouse and Rawson. Possibly the latter might make now a better lamp than the former. But his point was, and he challenged his learned friends to put their case higher than this, that they had made a better combination—that was to say, that they had made a better preparation of one of the elements of the combination, which was not described within the specification of the second claim of Mr. Edison. If carbon filaments were old, and he described five or six, though, of course, he could not pretend to exhaust them all, he could equally urge before their lordships that his learned friends could not get away from the meaning of the specification by saying "We have used an old carbon filament which is not the same as you have described, but which we have put in for the purpose of making a distinction"—because the patentee was entitled to claim "a glass receiver with a carbon filament through which the leading wires pass, the air having been exhausted in order to produce a vacuum." If his learned friend could have got up in court and said that it was not a carbon filament at all, the case would have been very different. His clients must have been beaten. But he respectfully urged upon their lordships that the extraordinary merit of Edison's invention was the simplicity of the combination, starting from a state of knowledge which would not have led people to the discovery, and announcing a genus of the widest description; and the merit of it was the wide description, which made it of necessity an infringement on the part of anyone, even if he could get hold of a better carbon, but still a carbon filament. If, too, his learned friends could have said, "Your description is bad, because there are numbers of carbon filaments made as you describe it, and it will not work"—if they could have said that a patent like yours could not make a working lamp—he admitted that it would have been very embarrassing. But when, on the contrary, he could say in his argument for the second claim that it was the only working lamp which had ever been made, he submitted that he made good the claim. He went further, and said that no diminution of sectional area would produce Edison's invention, starting from the point which Swan reached. On his instructions and on the evidence he did not believe that a carbon filament could be produced which would at all answer unless that filament were made before it was carbonised. The learned counsel then proceeded to define the meaning of a filament and to analyse the evidence upon the point when the Court rose.

In re the Pilsen Joel and General Electric Lighting Company.

This was a petition, heard before Mr. Justice North last Saturday, for the confirmation of resolutions for the reduction of capital lost or not represented by available assets. The capital of the company had been reduced on a former occasion, and as then reduced was represented by 100 £4 shares, fully paid up, and 28,000 £3 shares, £2. 5s. paid up. It was now proposed that £1. 15s should be written off the £4 shares, and £1 off the £3 shares, reducing them to £2 shares, with £1. 5s. paid up.

His LORDSHIP confirmed the reduction, directing the use of the words "and reduced" for a month.

Mr. Higgins, Q.C., and Mr. Rawson appeared in the matter.

COMPANIES' MEETINGS.

River Plate Telephone and Electric Light Company (Limited).

An extraordinary general meeting of this Company was held yesterday at the offices, 34, Walbrook, when the subjoined resolutions, which were passed at the meeting on the 1st inst., were submitted for confirmation as special resolutions :—

"1.—That it is expedient to effect an amalgamation of this Company, except as regards its Uruguay business, with the United Telephone Company of the River Plate (Limited), and that with a view thereto this Company be wound up voluntarily under the provisions of the Companies Acts, 1862 to 1883."

"2.—That Thomas Lloyd, of 34, Walbrook, E.C., Esq., and Charles Lionel Wingfield FitzGerald, of No. 4, Hercules-passage, E.C., Esq., be, and they are hereby, appointed liquidators for the purposes of such winding up, at a remuneration to be fixed by the Company."

"3.—That there be conferred upon the liquidators all the powers which can be conferred upon liquidators, under the provisions of the Companies Acts, and that they shall have the assistance of a consultative committee, consisting of Mr. Arthur Baker and Mr. William Cuthbert Quilter, with power to add one to their number."

"4.—That the remuneration of the liquidators be £250 each."

"5.—That the agreement expressed to be made between the Company of the first part; the United Telephone Company, of the River Plate, of the second part; Richard Rodgers, on behalf of the United River Plate Telephone Company (Limited), which is about to be incorporated, of the third part; the Consolidated Telephone Construction and Maintenance Company (Limited), of the fourth part; and Frank Williams Jones of the fifth part, be, and the same is hereby, approved, and that the liquidators be, and they are hereby, directed to adopt the said agreement on behalf of the Company, and to carry the same into effect, with power to agree to such modifications in the Articles of Association of the new Company as they think fit."

The SECRETARY (Mr. R. Rodgers) read the notice convening the meeting as above, and the minutes of the last meeting were taken as read, confirmed by the present meeting, and signed as correct by the Chairman.

The CHAIRMAN: Gentlemen, you have heard the notice calling the meeting, but before I proceed to move the several resolutions, I should like to state—what, perhaps, ought to have been stated at the last meeting, though I forgot to do so—that about two months ago Mr. Quilter and some friends of his acquired 7,000 shares in this Company, 5,000 of them being sold by the Company. Having stated so much, I do not think it is necessary to occupy your time, and therefore, without further preface, I will propose the first resolution (which he read).

Major FITZGERALD seconded the motion.

The CHAIRMAN asked if any shareholder wished to say anything. Receiving no response, he put the resolution and declared it carried unanimously. Continuing, he proposed the second resolution.

Mr. R. E. BATEMAN seconded the motion, which was carried unanimously.

On the motion of the CHAIRMAN, seconded by Major FITZGERALD, the third resolution was carried unanimously; as were also the fourth and fifth resolutions, which were proposed by the CHAIRMAN and seconded by Mr. BATEMAN.

Mr. C. L. W. FITZGERALD then proposed a cordial vote of thanks to the Directors for the way in which they had carried the amalgamation through, and also to the officers of the Company. Mr. Rodgers, in this country, and Mr. E. F. Powers, and the officers abroad, had, he was sure, done the best for the Company, and the sharedolders ought to give all those gentlemen a very hearty vote of thanks.

The motion was seconded and carried unanimously.

The CHAIRMAN: In the name of the Board I beg to tender you my grateful thanks for the kind manner in which Mr. FitzGerald has proposed the vote of thanks to us, and the cordial way in which you have carried it. As a Director, and for a short time Chairman of the Company, I can cordially confirm everything that Mr. FitzGerald has said respecting the very zealous and able manner in which Mr. Rodgers and our employés in the River Plate have carried out all their duties, and worked in the interest of the shareholders.

The proceedings then terminated.

NOTES.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended 17th inst. amounted to £4,665.

Okehampton.—At Okehampton, a small town on the borders of Dartmoor, a cabinet maker has lit up his premises with forty 20 candle-power lamps, motive power being derived from a turbine placed in the River Oke.

West India and Panama Telegraph Company.—The estimated traffic receipts of this company for the half-month ended the 15th December, are £2,278, as compared with £2,504 in the corresponding period of 1885.

Milan.—It is stated that Commander Carlo Erba, a well known Italian chemist, has given the sum of 400,000 francs for the foundation of a school of electricity, to be erected in the neighbourhood of the Institute of Technics at Milan.

Books Received.—From Mr. Thos. Murby we have received a copy of "The Arithmetic of Electrical Measurements, with Numerous Examples," by W. R. P. Hobbs, head schoolmaster of the Naval Torpedo School, Portsmouth.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending December 17th, 1886, were £3,856, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

The Lighting of the Streets of London.—We remark, with a certain inward satisfaction, that the columns of the daily press once more contain strongly—but not too strongly—worded complaints against the miserable inefficiency of the lighting in the London streets.

The Electric Transport of Force.—We learn from the *Bulletin des Sociétés d'Electricité* the MM. Rothschild are about to float a company with the object of carrying out the electric transport of force on methods recently shown by M. Deprez at Creil upon a commercial basis.

"Theory of Magnetic Measurements."—Prof. Nigher's book on the "Theory of Magnetic Measurements, with an Appendix on the Method of Least Squares," a notice of which appeared in our last week's issue, is published in this country by Messrs. Whittaker and Co., Paternoster-square.

Telephonic Extensions.—The South of England Telephone Company have effected telephonic communication between Northampton and Granville.—At Nottingham the National Telephone Company have opened a number of call offices, at which 3d. is charged for three minutes' conversation.

Long-Distance Telephony.—The telephone line between New York and Philadelphia is now in successful operation. At present 24 heavy copper wires are in use, but provision has been made for 70 wires. The tariff is fixed at $300 per month—say £1,750 per annum—and more lines are already required.

Eastern Telegraph Company.—The Eastern and South African Telegraph Company (Limited) notify that the coupons and interest warrants due on 1st January next, on their Five per Cent. Mortgage Debentures, will be paid on and after that date at the Banking House of Messrs. Barclay, Bevan, and Co., 54, Lombard-street. Coupons should be left three clear days for examination.

Lecture at Norwood.—A lecture was recently delivered by Mr. W. Lant Carpenter before a working class audience at Norwood, upon "Electrical Energy and its Uses," under the auspices of the Norwood Literature, Science, and Art Society. There was a crowded attendance, and the lecture, which was illustrated with numerous experiments, was followed with great attention throughout.

Electric Light for Pearl Fishing.—The steam yacht "Chic," belonging to Messrs. Alley and Maclelland, engineers, Glasgow, has been fitted up with a Brush dynamo for the purpose of suiting her for the pearl fishing in South Australian waters. The vessels at present there can only light up a depth of seven or eight fathoms, but it is anticipated that the "Chic" will be able to light up at seventeen fathoms.

Statistics of the Telephone in Europe.—The following figures, showing the present position of the telephone upon the Continent, have been published. Germany (State lines) 11,800 subscribers, average rental about £10; Italy, 8,590 subscribers; France, 7,000; Switzerland, 4,170; Belgium, 3,280; Spain, 800. The figures for our own country are not immediately available; probably, however, we should make a good second, even if we did not head the list.

The Lighting of Leamington.—We understand that the Leamington Town Council have accepted an offer from Mr. Arthur Chamberlain, of Birmingham, to light the town with incandescent electric light, at a cost of from 20 to 30 per cent. more than gas. Mr. Chamberlain proposes to lay in a temporary installation to illuminate the Parade and the principal public buildings with electricity during the celebration of the Queen's Jubilee.

Tender for Lighting Wanted.—The Gloucester Waggon Company invite tenders for the best and most economical mode of lighting one of their new workshops. Proposals may be for lighting by gas, electricity, or otherwise, and may include also methods applicable to raising steam and to heating iron rivets. Proposals to be delivered by the 18th January to the general manager at Gloucester, from whom further particulars can be ascertained.

Electric Lighting in Europe.—The Sociedad Electro-Dinamica are about to establish a central lighting station at the town of Chulilas, where a water power to the extent of 2,930 horse-power is available. They also talk of transmitting power to Valence, a distance of 56 kilometres.—The port of Kiel is to be provided with electric light; the installation will be carried out by Messrs. Schuckert, of Nuremberg.—In France a small town called St. Hilaire du Harcourt is to have a central lighting station.

Temporary Installation.—At the dance given at Mr. J. Bergthiel's house, 38, Warwick-road, W., on Wednesday, the 1st inst., the rooms were illuminated by 21 Woodhouse and Rawson incandescent lamps, the current being supplied from accumulators placed in the garden close by. The lamps were fitted in artistic shades, suspended by means of flexible conductors from the leads, which were stretched down the lengths of the rooms and covered with foliage and flowers. The work was done by Mr. Arthur Bergthiel, of Messrs. Woodhouse and Rawson.

Competition in Telegraphy.—The Postmaster-General, in reply to a deputation from the London Chamber of Commerce, among other things, referred to competition in cable work as tending to cheapen tariffs. Now, the head of the greatest monopoly that ever existed is hardly the person to talk in this strain. Either Mr. Raikes knows that, commercially, competition in the case of cables is another word for loss of capital or is he ignorant of the fact. If the latter, the sooner he obtains some elementary information on the subject the better.

Digitized by Google

THE BOSTON (U.S.) CENTRAL LIGHTING STATION.—We gave last week an interesting diagram showing the hourly consumption of current from this station. We may add that the plant, which at present has a capacity of rather less than 10,000 sixteen candle-power lamps, will shortly be increased to 40,000, when it will probably be the largest central station in existence. The new building will cover an area of 58ft. by 85ft., and will be two stories in height with a possibility of being raised to five stories. It will contain fourteen boilers and twenty engines.

WHISPERS IN THE LAW COURTS.—*Scene*—The Appeal Court. Lord Justice of Appeal (to Eminent Counsel): Do you mean that Van Choate's carbon was to be used for arc lamps and not for incandescent lamps? Eminent Counsel: For arc lamps, I think, my lord, but I am not quite certain. (Hurried consultation of bar. Second Eminent counsel to First Ditto, in whisper: Van Choate's carbon was for incandescent lamp without a globe, but *you'd better say arc lamps.*) Eminent Counsel: I find, my lord, that it *was* for arc lamps. (Left speaking.)

THE ADVANTAGES OF ELECTRIC POWER FOR MILLINERS' SHOPS.—Practical experience in the United States is said to have shown that a greater amount of work is accomplished by sewing machines when run by electric motors than by foot-power. Not only can the work be done with a higher speed of the machine, but considerable time wasted in bringing the machine up to full speed by the use of foot-power is saved. Less repairs are required, for the irregularity of the foot motion is destructive to the adjustment of the more delicate parts of sewing machines.

THE COST OF ELECTRIC LIGHTING IN AUSTRIA.—In a paper read before the Vienna Society of Electricians, Mr. F. Ross gave some figures showing the actual working cost of the electric light in certain theatres, where it has been in use for a sufficiently long period for a definite estimate to be formed. The prices quoted exhibited extreme variations; for instance, at Carlsbad, where the motive-power is obtained from a gas engine, 1,000 ampere-hours at 100 volts costs 54s., while at Bruun, with steam-power, the cost is only 18s. At Prague, also with steam-power, the cost is 26s.

THE PARIS-BRUSSELS TELEPHONE LINE.—It is announced that the Belgian Government (very sensibly in our opinion) no longer insist upon the adoption of the Van Rysselberghe system for this line, which will therefore consist of a complete metallic circuit of siliciun (or phosphor) bronze. On the other hand, the Belgian authorities have proposed the employment of the mixed system for the line which is projected between Verviers and Cologne, and the Germans are following the French example, and intimate their preference for a telephone circuit pure and simple for work of this description.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.—The Council of the Society of Telegraph-Engineers and Electricians have awarded the premiums at their disposal for the papers read during the past session as follows:—The Society's premium, value £10, to Mr. Alexander Bernstein, for his paper "On Low Resistance of Glow Lamps"; the Paris Exhibition premium, value £5, to Captain Sankey, R.E., for his paper "On the Electrolytic Deposition of Copper"; and the Fahie premium, value £5, to Mr. H. Kingsford, for his paper "On the Localisation of Faults in Submarine Cables."

LECTURE ON THE DEPOSITION OF DUST BY ELECTRICITY.—At the Bristol Naturalists' Society, a paper was recently read by Mr. W. P. Mendham, on the deposition of dust and smoke by electricity. A description was given of the process, which was suggested by Dr. O. Lodge, and is now employed with considerable success for causing the rapid deposition of the fumes of sublimated lead, by means of the action of powerful Holtz or Wimshurst machines. In the discussion which ensued, it was pointed out that the process was not adapted for use in depositing either coal dust in mines or flour in mills, on account of the danger of explosion.

LIGHTNING CONDUCTORS.—The Minister of Public Instruction of the French Government has recently submitted to the Academy a series of questions with regard to the precautions which should be taken for the protection of buildings from lightning, particularly in the case of buildings which are roofed with metal. As might have been anticipated, the reply of the Academy was to the effect that all such masses of metal should be carefully connected with the conductors, that for extensive buildings several conductors should be affixed at different points, and that it was above all things necessary to see that the conductors make thoroughly good earth connection.

THE WOODHOUSE AND RAWSON MANUFACTURING COMPANY'S EMPLOYÉS' ANNUAL DINNER.—The third annual dinner of the *employés* of the Woodhouse and Rawson Electrical Manufacturing Company was held at the First Avenue Hotel on Saturday evening, when the chair was taken by Mr. Rawson. A very pleasant evening was spent by all present, the musical portion of the entertainment being far above the standard of merit which is usually attained on such festive occasions. Mr. Woodhouse had not yet sufficiently recovered from his recent severe illness to enable him to take part in the proceedings; but we are glad to be able to state that he is now very much better, and it may be hoped that his health will shortly be fully restored.

A LARGE EDISON MACHINE.—The French Edison Company have just completed, in their factory at Ivry, the construction of an Edison dynamo, to give 1,000 amperes and 125 volts at 350 revolutions. The machine is intended for lighting the stage of the Paris Opera House; and floor space being limited some considerable modifications have been made in their usual design. The armature rotates between two pairs of field-magnets set vertically so as to give consequent poles. The machine is purely shunt wound, and a field current of only 25 amperes gives an induction of 5,000 C.-G.-S. units. The full current of 1,000 amperes is taken off by three pairs of brushes. Although the weight of the machine is nearly 10 tons, it is mounted upon a slide bed. The preliminary trials are said to have been very satisfactory.

FRANCO-GERMAN URBANITIES.—The following incident, which has recently been the subject of comment in the columns of the French scientific press, is a little amusing. At the close of a series of articles in a certain electrical journal there appeared a paragraph eulogising the general excellence of design and workmanship of the scientific instruments made in Germany. A leading firm immediately writes to express their extreme astonishment, and that of all persons to whom they have shown the article, that it should be possible for statements so "unpatriotic" to appear in a French journal; while another writer roundly asserts that German instruments cannot bear a moment's comparison with those manufactured in France. Moreover, they are—according to this authority—never of original design, being always copied either from French or English makers.

PROPOSED CENTRAL STATION WITH TRANSFORMERS AT RHEIMS.—A number of isolated installations of electric light already exist at Rheims, most of which obtain motive power from engines already in use for other purposes. With proper precautions such arrangements can, as a general rule, be made to work very well indeed, but for some reason or other the good

Digitized by Google

people of Rheims do not seem to be quite satisfied with their present arrangements. Or perhaps it may be nearer the mark to suppose that having experienced the advantage of the electric light for themselves they are anxious to extend it to their neighbours. Anyhow, a movement has been set on foot in the town, and is being warmly supported by the present owners of isolated installations, for the establishment of a central lighting station. It is at present intended to make use of transformers, which, in the opinion of the *Bulletin Internationale de l'Electricité*, "assuredly furnish the true solution of the electric lighting of towns."

"Dynamo" Telephones.—Prof. Silvanus Thompson pointed out some time ago that in all probability the most successful solution of the problem of long-distance telephony, and also that of overcoming inductive disturbance, would result from the discovery or invention of a method which would enable us to employ a current many hundreds or even thousands of times stronger than those at present used in telephony. Prof. Thompson has recently constructed some remarkable instruments with a view to carrying out this idea. We shall hope shortly to give further details with regard to the performance and construction of these instruments; in the meantime we may say that they are based upon the idea of utilising an armature constructed very much after the pattern of the armature of a dynamo (either of the ring or drum type), and mounted between field-magnets. Instead of being capable of rotation it is, however, supported upon an elastic axle, which permits it to vibrate to and fro over a small arc. To a point upon the periphery of the armature is affixed a pivoted bar, the other end being attached to the centre of a diaphragm.

The Lighting of Trains.—"The evening traveller upon certain of our railways," says the *Pall Mall*, "is apt to think of Milton, not as a poet, but as a prophet: 'Yet from these flames no light, but rather darkness visible.' Nothing radical in the shape of reform, travellers may depend upon it, will ever be attempted by these very conservative companies until the regular passengers take to holding indignation meetings on the departure platforms at our great metropolitan stations. There is sufficient of novelty in this suggestion to ensure for such demonstration a great success. Who will lead the way?" The experiments which have been carried on since March last on the Lille and Brussels lines with a bichromate battery are said to have proved perfectly successful. The cars from Paris to Brussels can make five journeys in each direction, averaging a lighting period of seven hours, before recharging is required. This is said to occupy only five minutes, though we should scarcely like to guarantee the accuracy of the statement. What, however, is more important is the price. This is given as *1·1fr. per candle-power per hour*. For the sake of the inventor we shall hope that this ought to read "per lamp-hour of twenty candles."

An "Open" Incandescent Lamp.—Messrs. Lyman and Wheeler, of Washington, have introduced a somewhat novel form of incandescent lamp, which may perhaps have an important future. The idea is not altogether new, for it is in reality a "Lampe Soleil," adapted for use upon the scale of incandescent rather than arc lighting. The arrangement may be briefly described as consisting of a shallow cup of refractory material, having a tube of the same substance projecting on either side. The cup is filled with amorphous zirconia (or other similar substance), and a platinum wire passing through either tube almost makes contact in the centre. When a current is passed through, the zirconia is raised to a white heat—but how the current is induced to start we are not told. The idea is to have the lamp close under the ceiling, and diffuse the light from a whitened reflector, so that the actual incandescence is concealed from the eye. This is undoubtedly the principle upon which artificial light ought always to be supplied, if it can be done. We shall be very glad to hear that the device proves sufficiently practicable and economical for general service, but we fear that there are serious difficulties to be overcome before this can be accomplished.

The "Union" Storage Battery.—From *The Times* of Saturday last we learn that a new battery has appeared under the name of the "Union" storage battery. We gather that this cell belongs to the class which lies upon the somewhat ill-defined border line between primary and secondary cells. That is to say, it is proposed to remove the exhausted plates from the cells and cast them away for re-charging. We know no essential reason why such a system should not eventually become a thorough commercial success. But as it is obvious that it can scarcely be made to pay until a considerable number of subscribers have been secured, it is to be feared that such success may be some time in coming. As we have not had an opportuntiy to inspect this battery on our own account we can only record such particulars as are to be gathered from *The Times* paragraph. Of these the only important statements are that a cell of thirteen plates, measuring (externally) 11in. by 7in. by 6in., weighs 2·0lbs., and has a capacity of 115 ampere-hours. The positive plates consist of spongy lead, and the negatives "of a specially prepared" substance. Various advantages are claimed, such as absence of buckling, a firm hold on the active material, high conductivity, and a capacity for being transported and stored ready for use in a dry condition.

Continuous Current Transformers.—So far as we are aware, Messrs. Paris and Scott, of Norwich, are the only firm who have hitherto taken up in earnest the question of effecting the transformation of high tension continuous currents into low tension currents. This they have accomplished by the simple device of winding an armature with two circuits, and arranging to run one half as a motor by means of the high tension current, and allowing the other half, working as a dynamo, to generate current at a lower potential. Of course the system can scarcely be expected to lend itself to the distribution of electricity so readily as does the class of transformers in which alternating currents are employed—for the mechanical motion must not only add largely to the cost of the apparatus, but will also tend to prohibit its use for general domestic lighting. At the same time we feel sure that there must be a large number of instances in which such an apparatus will prove of very great value. It has recently been pointed out by M. Cabenallas that the principle is by no means a new one, having been suggested by M. Gramme and described by M. A. Niaudet in the year 1875. The field is therefore thrown open to all comers, so far as the general principle is concerned, although doubtless there will be plenty of room for inventive talent and constructive skill in the development of the most satisfactory arrangement of detail.

The Glasgow Underground Railway.—We are enabled to give the following additional information as to the interesting experiments on train lighting which are now in progress on the underground lines of the North British Railway Company at Glasgow:—The central rail is raised on insulating supports somewhat higher than the rails on each side of it. From underneath each carriage two pulleys or small wheels are suspended, one at each end of the carriage. These pulleys run on the conducting rail, and convey the current from the rail by suitable connecting wires to the incandescent lamps

Digitized by Google

within each compartment of the carriage. There is a spring attachment to the pulley, which allows it to rise as far as necessary should the carriage be pressed down a little by a heavy weight of passengers. The pulley has also a horizontal movement, so that between the two motions it may freely run up or down the short slope in which the conducting rail terminates at the mouths of the tunnel. Only one of these pulleys would be required on each carriage, but it is found that the two give a steadier light. The central rail terminates at the end of the tunnel. The wire from the pulley leads to two incandescent Swan lamps, of 16 candle-power each, in the roof of each compartment. Only one of these is used at a time, and in the event of it breaking the second one by a suitable automatic arrangement lights up. The return wire is connected to the wheels of the carriage, and thence the current passes to the ordinary rails, through which the circuit is completed to the dynamo. The great advantage of this system is that there is no connection between the carriages, each carriage taking its own supply of current from the central rail, and that whether the train is standing or in motion. The carriages can thus be shunted in the ordinary way, and there are no connections to be made or broken.

THE JULIEN TRAMCAR IN NEW YORK.—A correspondent of the Philadelphia *Daily News* gives some rather amusing details respecting the introduction of the Julien system on the New York tram lines. According to this statement it appears that an American who happened to see the system in operation at Hamburg introduced himself to the inventor with a view to doing business for him in the States. M. Julien found it extremely difficult to swallow some of the statements which were placed before him, with, perhaps, somewhat injudicious haste by the Yankee, statements which, nevertheless, we have no doubt are perfectly true. Such, for instance, that in Philadelphia alone there are 343 miles of street railways, and that New York and Brooklyn together contain more tramcars than the entire state of Belgium. However, having at length inspired M. Julien with the necessary confidence in his veracity, the Yankee went back to New York and speedily sent an order for a set of batteries and a motor, specifying that they would be required to drive a car to seat thirty persons. We give the rest of the story in the words of the correspondent, from whom we have obtained the above details:—"Mr. (*sic*) Julien accordingly supplied batteries capable of producing power sufficient to carry thirty per.ons. Mr. Bracker sent him a frantic cable-gram, stating that the motor would have to be sufficiently powerful to move seventy passengers. Mr. Julien was serene in his belief that it would have to do nothing of the sort, for the very simple and apparently very conclusive reason that the car could only seat thirty persons. In Belgium and France, you must understand, when every seat in a street vehicle is taken a placard bearing the simple announcement, 'Complet,' is displayed, and while it hangs forth no one attempts to enter the car. It took some time to explain to Mr. Julien that in America railway officials crowd even as many as one hundred persons into a single street car, and if they did not do it they would be roundly abused by the average man, to whom the idea of staying his frantic rush through life by obliging him to 'wait for the next car' would be maddening. So Mr. Julien had to supply the car with new batteries, and it arrived in New York several weeks ago, in readiness to carry seventy passengers. Those passengers have now been carried."

THE ISLE OF MAY LIGHTHOUSE.—A correspondent from Edinburgh kindly sends us the following additional details with regard to the Isle of May lighthouse, which will be read with interest. It will be noted that the optical apparatus enables the spherical illumination of 30,000 candles which is given by the arcs to be concentrated in any one direction, so as to give a beam actually 1,000 times more intense:—"Her Majesty's Commissioners of Northern Lights steam yacht 'Pharos,' left Granton on Saturday, the 18th, having the Commissioners on board, for the purpose of inspecting the new electric light on the Isle of May. The Commissioners present were the Right Hon. the Lord-Advocate, Q.C., C.B., M.P., LL.D., M.S.T.E., the Solicitor-General, Q.C., M.P., the Sheriff of Inverness, who was Commodore for the day, the Sheriff of Aberdeen, the Sheriff of Berwickshire, the Sheriff of Caithness, who is *ex officio* Lord High-Admiral of the Pentland Firth, the Sheriff of Fife, the Sheriff of Forfarshire, Mr. Duncan, advocate, secretary, Mr. Stevenson, engineer, Mr. N. D. Macdonald, Mr. Ivory, and the Rev. Mr. Tait. Some difficulty was experienced in landing on the island as there was a good deal of sea on. After some difficulty the Commissioners were landed and were shown over the buildings. On arriving at the engine house a minute inspection was made of the the engines and dynamos, which were set running. One of the lights was shown by the resident engineer in an adjoining room, the brilliancy of which was blinding. Afterwards the lighthouse and the lantern were inspected. An account of the light appeared in last week's *Electrician*. The resident engineer informed the Commissioners that the light was first started on 1st December, and ran 16 hours without a hitch without having been previously tried. They were also informed that the light had run without a single break every night since then. Also that the experiment had been made of changing from one engine and dynamo to the other, as in the case of accident, and the light was only extinguished for 15 seconds. The electric lamp is changed once an hour to allow it to cool, which change takes three seconds. The light is about 25,000 candle-power, but when seen from the water gives a flash equal to 3,000,000 candles (which can be increased to 6,000,000 candles in a fog), being increased to this amount by the dioptrics. The commissioners returned to Edinburgh at night. At a distance of 50 miles the flash of this light looks as bright as an ordinary oil one does at half a mile."

THE SUBMARINE BOAT "NAUTILUS."—On Monday last we had the pleasure of witnessing some experiments with the submarine boat "Nautilus," at the Tilbury Docks. The "Nautilus" is a cigar-shaped boat, built of steel, 60ft. in length and 8ft. in diameter amidships. She is propelled and steered by electricity. Elwell-Parker cells are employed, and the same firm supplied the switches and other electrical fittings. Two Edison-Hopkinson machines, by Mather and Platt, are used as motors, each machine driving one of a pair of twin screws, which are mounted directly upon the armature shafts, and run at 750 revolutions per minute. The number of cells is 104; they are divided into two separate batteries, one for each motor, and each yields 180 amperes at 100 volts for six hours. The boat is therefore provided with no less than 45 horse-power. The batteries weigh over 10 tons, and the motors very nearly a ton each. At a slow speed the boat can travel at least 75 miles without recharging the cells. The principle upon which the "Nautilus" can be submerged at will is that of displacement. Four large hollow cylinders fitted in stuffing boxes project from the sides, and can be drawn in or pushed out by manual power under the control of the crew. The advantage of this particular arrangement is that the vessel can sink either when running at full speed or when riding at her moorings, and whether motive power is ready or not. On going on board the boat we found the space below deck "cribbed, cabined, and confined" even beyond what we had expected;

Digitized by Google

a voyage of fifty miles on board such a craft would be anything but a pleasure trip. However, the "Nautilus" is designed for stern duties, and not for pleasure or comfort. One of the difficulties of submarine navigation is the impossibility of knowing in which direction to steer, except in an open sea (where after her course has been laid on the surface she has only to go straight ahead), and another is the difficulty of stopping or reversing the motion of the boat when once under weigh. These circumstances did not permit any speed trials to be undertaken in the Tilbury Docks. The boat crept about at a slow speed under water, and was steered by the aid of a telephone connected with a skiff which followed her movements. Although the real capabilities of the boat as an offensive weapon were not, therefore, very fully demonstrated, yet we do not entertain any doubt that with the facilities afforded by electric propulsion she is capable of rendering service of the highest value, particularly in the defence of unprotected coast towns. If only some method could be devised whereby she might be steered below water with the same certainty as upon the surface a great advantage would be gained. Possibly some electrician will be able to suggest a means for doing this.

THE LIGHTING OF THE BRIGHTON PAVILION.—At a meeting of the Brighton Town Council on Thursday last, it was stated that, there having been numerous complaints in reference to the present system of lighting the rooms by gas, and the Liverpool and London and Globe Insurance Companies having, in consequence of a report made by Mr. Heaphy, C.E., refused to insure the building if the electric lighting was continued, the committee requested Mr. W. H. Preece, F.R.S., to inspect the pavilion and report. Mr. Preece, after stating that the present wiring was dangerous, said he estimated the cost of putting the present installation into thorough working order at £412. 15s., and secondary batteries would cost another £600. He added that as it was imperative that the existing chandeliers should be used, owing to the peculiarity of the rooms, special wire would have to be obtained, and none but the most experienced workmen should be entrusted with the job. During the three years that had elapsed since the work at the Pavilion, considerable experience had been gained in the proper mode of wiring buildings. In conclusion, he deprecated any proposal to abandon the electric light now that £5,000 odd had been spent upon it, and he pointed out that though the cost of electric lighting was twice that of gas they would have not only its superiority as a light but its greater comfort, its freedom from vitiation of air, its absence of destructive qualities to decorations and fittings, its greater security, and its greater attractiveness to visitors and hirers of the rooms. The committee supplemented this report by stating that Mr. Heaphy had informed them that if Mr. Preece's recommendations were carried out they would fully satisfy the requirements of the insurance companies for which he acted. The committee had also made inquiries as to the cost of improving the arrangements for lighting the pavilion property by gas, regulating the pressure, improving the lighting, and economising the consumption of gas, and they had received from Mr. Sugg an approximate estimate amounting to £1,500, of which about £1,000 would be for the Royal Pavilion proper. They recommended that the use of the electric light in the pavilion and dome, the picture galleries, library, and museum should be resumed; that secondary batteries should be employed sufficient for 10 hours lighting of the banqueting room, corridor, saloon, and one drawing room. To accomplish this, 106 cells would be required at an estimated cost (including fixing) of £660; that the relaying of the wires in grooved boarding, and the other recommendations in Mr. Preece's report should be carried out; that the services of an electrician at £2 per week should be secured, and that he should commence his duties concurrently with the carrying out of the suggested additions and alterations.

A DISTINCTION *with* A DIFFERENCE.—We were recently somewhat surprised to learn that in certain quarters which might have been supposed to be tolerably well posted up in such matters there exists a decided misconception as to the precise difference between the accepted significations of such everyday terms as "electromotive force" and "difference of potential." We have always understood that electromotive force may be defined as *that which causes* a difference of potential; and this definition is not by any means a mere scholasticism, for the simple reason that in a closed circuit containing a single source of electromotive force, the latter has (or may have) only one fixed value, while the value of the "difference of potential" depends upon the position in the circuit of the points between which this difference is measured, and may therefore have any number of different values from zero up to that of the E.M.F. itself; while at the same time all values of potential difference are caused by, and are proportional to, the E.M.F. Hence in a dynamo we speak of the "difference of potential at the terminals," or at the lamps, which is caused by "the internal electromotive force." That an attempt should at this date be made to upset an established convention of so useful and convenient a character is, we think, decidedly to be deprecated. The following paragraph, which appears in a contemporary journal, has induced us to enter this protest:—"A correspondent of the *English Mechanic* quotes a passage from the *Electrical Review* as follows:—'When the external resistance approaches the internal resistance, the E.M.F. of the cells will be reduced, and if the external was made equal to the internal resistance the E.M.F. would be but half that indicated when the external resistance was high. How is this? I thought that the E.M.F. of any cell depended solely upon the materials composing the two plates, and the composition of the battery acid representing electro-chemical actions of various kinds, each of which produced its own particular E.M.F.'" On this the journal referred to subjoins, "The above statement is correct. The querist confuses the full potential, or E.M.F. on open circuit, with the free potential when the battery is working. If he will measure the E.M.F. of a cell which is not connected up with any exterior circuit, he gets the full potential between its terminals, but if he joins the terminals up to a resistance equal to the internal resistance of the cell, he will find that only half the potential is free. If he proceeds still further, and short circuits the cell with a thick piece of copper wire, he will find the free potential between the terminals reduced to practically zero." For ourselves, we beg leave to assert that, in accordance with the views which we had thought to be universally accepted, the correspondent of the *English Mechanic* is perfectly correct in his assumption that the E.M.F. of the cell is a constant quantity, subject, however, to the influence of such secondary chemical re-actions as may take place in the cell, and also to a certain slight extent depending upon temperature, but otherwise quite independent of the resistance of the circuit, both external and internal. The "difference of potential" at the terminals of the cell is, upon the other hand, a function of the E.M.F. and of the external and internal resistance, and there is nothing in the correspondent's query to show that he was not perfectly well acquainted with these elementary facts. We trust that it is not proposed to speak in future of the "free potential" of a dynamo machine.

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 121.)

We have seen that a wire conveying a current exerts a force upon a magnetic pole in its neighbourhood. The magnitude of this force depends upon the strength of the magnetic pole, being proportional to it, the strength of the current, being proportional to it also, the length and shape of the wire, and the position of the pole relative to the several parts of the wire. Upon this action the electromagnetic system of units is based.

In this system the unit of current is first defined, as follows:

The electromagnetic unit of current is that current which, flowing in a wire one centimetre long, every point of which is in the same plane, and distant one centimetre from a unit magnetic pole, which is also in the same plane, exerts through air upon the unit pole a force of one dyne.

From this it appears that the wire must form an arc of a circle of one centimetre radius, and having the unit pole at its centre. The force exerted upon the pole will, of course, be perpendicular to the plane of the wire.

In all electromagnetic measurements, instead of employing a single centimetre of wire, a coil containing several turns of wire is used, the length of wire and the position of every turn being accurately determined. The wires which bring the current to and from the coil may then enter and leave the coil at nearly the same point, and if they are insulated and twisted round one another, their effect upon a magnet at the centre of the coil will be negligible.

If a single circle of wire of one centimetre radius conveyed a unit current. a force of 2π dynes would be exerted on a unit magnetic pole at the centre of the coil. If the size of the circle be varied, the force exerted on a unit pole at its centre will vary inversely as its diameter.

The absolute unit of electromotive force is that electromotive force which does unit work (one erg) in unit time (one second), when urging a unit current through a conductor.

Or we may define the unit of electricity as that quantity which passes in one second across a section of a conductor, conveying the unit current, and thus define the unit electromotive force as that which does unit work on the unit of electricity, so that it corresponds to unit difference of potential.

The absolute unit of resistance is the resistance of a conductor in which a unit electromotive force produces a unit current.

Hence, in a conductor of unit resistance, a unit electromotive force produces unit current, and does a unit of work (one erg) in a unit of time (one second).

The absolute units above defined are not those adopted in practice, the absolute units of electromotive force and of resistance being far too small for convenience, while the absolute unit of current is somewhat large.

The ampere, the unit of current adopted in practice, is one-tenth of the absolute unit. The absolute unit is therefore equal to ten amperes, which is about the current employed for arc lamps of 1,000 candle-power. Such a lamp consumes about two-thirds of a horse-power. For a horse-power is equal to 7,458,000,000 ergs per second, and an arc lamp taking ten amperes consumes 5,000,000,000 ergs per second. Hence, the electromotive force required to light such an arc lamp is 5,000,000,000 absolute units. The volt, which is the unit adopted in practice, is equal to 100,000,000 or 10^8 absolute units, and therefore the E.M.F. required to light the arc lamp is 50 volts.

The unit of resistance, or the ohm, is the resistance of a conductor in which the unit of electromotive force, or volt, can produce the unit of current, or ampere—that is, the resistance of a conductor in which 10^8 absolute units of electromotive force can produce $\frac{1}{10}$th of an absolute unit of current, and this resistance is clearly 10^9 or 1,000,000,000 absolute units of resistance.

Since the work done by an electromotive force E in sending a current C is E C ergs per second, if all the quantities are in absolute units, it follows that an electromotive force of one volt sending a current of one ampere will do $10^8 . \frac{1}{10} = 10^7$ ergs per second. This rate of doing work is called a *watt.*

Again, the work done by a current C in flowing through a resistance R is C^2R ergs per second, if all the quantities are expressed in absolute units. Hence, one ampere flowing through an ohm will do $(\frac{1}{10})^2 10^9 = 10^7$ ergs per second, which is the same as that done by a volt in urging an ampere, as of course it should be.

A watt	$= 10^7$ ergs per second.
An ohm	$= 10^9$ absolute units.
A volt	$= 10^8$ absolute units.
An ampere	$= 10^{-1}$ absolute units $=$ volt $\div$ ohm.
A horse-power	$= 745{\cdot}8$ watts.

The horse-power consumed in sending any current may be obtained by multiplying the E.M.F. expressed in volts by the current expressed in amperes, and dividing the product by 745·8 (or for practical purposes by 746). If all the energy is consumed in overcoming resistance, the horse-power may be determined by multiplying the square of the current expressed in amperes by the resistance expressed in ohms, and dividing the product by the same number as before.

If an incandescent lamp is ignited by an E M.F. of 60 volts, sending a current of 1·2 amperes, the rate of doing work will be 72 watts or 720,000,000 ergs per second. A foot pound is equal to about 13,560,000 ergs. Hence the work done in lighting the lamp will be equal to $\frac{7200}{1356}$ foot pounds per second, or about 191,150 foot pounds per hour. The amount of work which, if entirely converted into heat, would raise 1lb. of water 1°C., is 1,390 foot pounds. Hence, the heat developed in the incandescent lamp in one hour would raise nearly 1·38lbs. of water from the freezing to the boiling point. The heat developed by the combustion of five cubic feet of coal gas would raise nearly 18lb. of water through the same range of temperature.

The absolute unit of quantity is the quantity of electricity which is conveyed in one second by the unit current.

The absolute unit of capacity is that of a condenser which can be charged with the unit of quantity by the unit of electromotive force.

A farad is the capacity of a condenser which, when charged to the potential of a volt, contains an amount of electricity equal to that which is conveyed in one second by a current of one ampere.

A farad is therefore equal to 10^{-9} absolute units of capacity. A microfarad is the millionth of a farad, and is equal to 10^{-15} absolute units of capacity.

Since action and reaction are equal and opposite, it follows that the pole of a magnet will exert a force upon a wire conveying a current equal and opposite to that which the wire exerts upon the pole. Hence, a unit magnetic pole placed at the centre of a circle of wire of one centimetre radius in which a unit current is flowing, will exert a force of one dyne on every centimetre of the wire. But a unit magnetic pole exerts a force of one dyne upon another unit pole at a distance of one centimetre—that is, produces a magnetic field of unit strength at a distance of one centimetre. Hence, replacing a magnetic pole by the field which it produces, we see that a centimetre of wire conveying a current, and placed in a unit magnetic field, so as to be at right angles to the lines of magnetic force, will be acted upon by a force of one dyne, urging the wire at right angles to its own direction, and at right angles to the magnetic lines of force. Thus, if the lines of force pass from north to south, and the current flow from east to west, the mechanical force upon the wire will act vertically upwards. If the lines of force pass vertically downwards, and the current flow from west to east, the mechanical force on the wire will urge it from south to north.

Suppose there are two straight metal bars running parallel to one another from south to north. Let a third bar be capable of sliding in contact with each of these bars, and let a current enter the south end of the bar which lies west of the other, pass through the cross bar, and return to the battery from the south end of the eastern bar. Suppose that the whole system is in a uniform magnetic field and that the lines of force pass vertically downwards. Let the strength of the field be H, the strength of the current C, and let the length of the sliding bar, *i.e.*, the distance between the parallel bars, be *l*, all these quantities

Digitized by Google

being expressed in absolute units. Then there will be H lines of force passing through every centimetre of the horizontal plane which contains the conductors. The cross wire will be urged at right angles to itself and to the lines of magnetic force, and will tend to slide from south to north. Since unit force acts on each centimetre of a wire conveying unit current in a unit magnetic field, the force upon this wire will be HCl dynes, since its length is l centimetres, the current conveyed is C units, and the strength of the field H. If the wire move in obedience to this force work will be done by the electromagnetic forces, and the requisite energy must be derived from the battery urging the current, since there is no other source of energy in the system which can be drawn upon. If the current remain the same as when the wire is at rest, the whole of the work done by the battery will be converted into heat; but if the current be diminished, the work done by the battery will be diminished in proportion, but the heat generated will be diminished at a faster rate, being proportional to the square of the current, and then, and only then, will the work done by the battery exceed the heat generated and be able to furnish the energy required to do the necessary mechanical work on the wire. Suppose that E is the E.M.F. of the battery, R the resistance of the circuit which we suppose constant, then $E = CR$ if C be the current flowing when the crossbar is stationary. Let C' denote the current when the bar is moving with a velocity of v centimetres per second. Then the resultant electromotive force in the circuit must be $C'R$, and there must therefore be an electromotive force, e, introduced by the motion, which electromotive force opposes the battery and is equal to $(C - C')R$. The magnitude of this opposing E.M.F. may be thus determined :—

The mechanical force acting on the cross conductor is $HC'l$. Hence the mechanical work done in a second is $HC'lv$ ergs. But the work done by the battery is EC' ergs, or CRC' ergs, since $E = CR$, and the energy converted into heat is C'^2R ergs. Hence the work done by the battery in excess of the heat generated is $C'CR - C'^2R$ or $(C - C')C'R$ ergs. Therefore by the conservation of energy,

$$(C - C')C'R = HC'lv,$$

or,

$$(C - C')R = Hlv,$$

that is, the electromotive force opposing the battery which is introduced by the motion of the conductor is equal to Hlv, which is the number of magnetic lines of force cut across in a second by the conductor of length l moving with velocity v through a magnetic field in which there are H lines of force per square centimetre.

(*To be continued.*)

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XXXIV.

BY OLIVER HEAVISIDE.

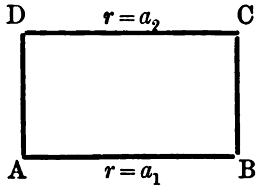
(*Continued from page 11.*)

Extension of the Preceding to Include the Propagation of Current into a Wire from its Boundary.

The first step to getting out of the wire into the dielectric occurs in Sir W. Thomson's theory, Section XXXII. We certainly get as far as the boundary of the wire. To some extent we make progress in adopting (same section) Maxwell's idea of the continuity of the conduction and the dielectric current, when the conduction current is discontinuous itself. Further progress is made (Section XXXIII.) in introducing the electric force of inertia and the magnetic energy, so far as dependent on the first differential coefficient of the current with respect to the time, assuming the magnetic field to be fixed by the single quantity C, the wire current, just as the electric field is fixed by the single quantity V, the potential difference of the two wires at a given distance.

But the magnetic machinery does not move in rigid connection with the wire current, as is implied in the specifications of the magnetic energy by $\frac{1}{2}LC^2$, like that of the electric energy by $\frac{1}{2}SV^2$, L and S being the inductance and the electrostatic capacity, per unit length of line. In going further, I believe the following to be the most elementary method possible, as well as being pretty comprehensive. To fix ideas, and simplify the nature of the magnetic field, let the line consist of two concentric tubes, separated by a dielectric non-conducting tube. The dielectric is to occupy our attention mainly in the first place. Let a_1 and a_2 be its inner and outer radii, a_0 the inner radius of the inner tube, and a_3 the outer radius of the outer. Find the connection between the longitudinal electric force at the inner and outer boundaries of the dielectric tube, and the E.M.F. of the condenser, and the E.M.F. of inertia, so far as it depends upon the magnetic field in the dielectric.

Let ABCD in the figure be a rectangle in a plane through the common axis of the tubes, AB being on the inner and CD on the outer boundary of the dielectric, both of unit length. Let the current be from A to B in the inner tube, in which direction x is measured, and therefore from C to D in the outer tube. These currents are not precisely equal under all circumstances, but are so nearly equal that we can ignore the longitudinal current in the dielectric in comparison with them; thus the current C in the inner necessitates the same current C in the outer tube. The lines of magnetic force are directed upward through the paper, and the intensity of force is $2C/r$ at distance r from the common axis of the tubes.



The total induction through the rectangle is therefore

$$\mu_2\int_{a_1}^{a_2}\frac{2C}{r}dr = \left(2\mu_2\log\frac{a_2}{a_1}\right)C = L_0C,$$

if μ_2 be the inductivity of the dielectric, and L_0 the inductance of the dielectric per unit length of line.

Now, the rate of decrease of the induction with the time, or $-L_0\dot{C}$, is the E.M.F. of inertia in the circuit ABCD in the order of the letters. But if E and F are the longitudinal electric forces in AB and DC, and V and W the radial forces in BC and AD, another expression for the E.M.F. in the circuit is $E - F + V - W$. But as AB and CD are of unit length, $V - W = dV/dx$. Hence

$$E - F + \frac{dV}{dx} = -L_0\dot{C}, \quad \text{or} \quad -\frac{dV}{dx} = L_0\dot{C} + E - F \quad (73b)$$

Next, let Γ_1 and Γ_2 be the longitudinal current densities at the boundaries of the conductors, ρ_1 and ρ_2 their resistivities, and e_1, e_2 the impressed forces, if any, in them. Then, by Ohm's law,

$$e_1 + E = \rho_1\Gamma_1, \qquad e_2 + F = \rho_2\Gamma_2;$$

and therefore

$$E - F = \rho_1\Gamma_1 - \rho_2\Gamma_2 - e, \quad . \quad . \quad . \quad (74b)$$

if $e = e_1 - e_2$. Thus e is the impressed force in the circuit per unit length, irrespective of how it is divided between the inner and the outer conductor. Also, e is supposed to be longitudinal.

Now use (74*b*) in (73*b*), making it become

$$e - \frac{dV}{dx} = L_0\dot{C} + \rho_1\Gamma_1 - \rho_2\Gamma_2. \quad . \quad . \quad (75b)$$

We now require to connect Γ_1 and Γ_2 the current densities at the boundaries of the conductors, with the total currents in them; representing these connections thus,

$$\rho_1\Gamma_1 = R_1''C, \qquad -\rho_2\Gamma_2 = R_2''C, \quad . \quad . \quad (76b)$$

we require to find the forms of R_1'' and R_2'', one for the inner, the other for the outer conductor. If this be imagined to be done, and we put

$$R'' = L_0(d/dt) + R_1'' + R_2'',$$

the equation (75*b*) becomes

$$e - \frac{dV}{dx} = R''C = L_0\dot{C} + R_1''C + R_2''C \quad . \quad . \quad (77b)$$

Digitized by Google

wherein R″ is known. The complete scheme will therefore, be,

$$e-\frac{dV}{dx}=R''C, \quad q=SV, \quad -\frac{dC}{dx}=\frac{dq}{dt}=S\dot{V} \quad (78b)$$

which should be compared with (71*b*) and (72*b*). As for the equations of V and of C, they may be obtained by elimination, but it is unnecessary to write them at present.

We have supposed R_1'' and R_2'' to be known. The question is, then, how to find them. We know that in steady flow they must be R_1 and R_2, the steady flow resistances of the conductors. We know, further, that they are $R_1+L_1(d/dt)$ and $R_2+L_2(d/dt)$, when only the first derivative $\dot{C}$ of the current is allowed for. Now, we know that, under all ordinary circumstances, the length of a wire must be a very large multiple of its diameter before the influence of the electrostatic charge becomes sensible. When it does become sensible the current is of a different strength in different parts of the line during the setting up of a steady current. But in a section of the line which, though long compared with the diameter of the wire is short compared with its length, the current changes insensibly, even when the change is very great between the current strength in that section and in another, which, by contrast, may be called distant from the first.

It is clear, therefore, that we shall come exceedingly near the truth if, in the investigation of the function R_1'' we altogether disregard the change in strength of the current in passing along the line. This amounts to ignoring the small radial component of the current in the conductors, and making the current quite longitudinal. This is only done for purposes of simplification, and does not involve any physical assumption in contradiction of the continuity of the current; for we join on the dielectric current to that in the conductors, by means of the equation of continuity, the third of (78*b*).

The determination of R_1'' and R_2'' is thus made an electromagnetic problem, of which I have already given the solution. See equation (50*b*), Section XXX (August 6th, 1886), where, the first big fraction represents R_1'' for the inner conductor and the second R_2'' for the outer. The separation of these into even and odd differential coefficients, thus

$$R_1''=R_1'+L_1'p,$$

is of principal utility in the periodic applications. It may be perhaps as well pointed out that in the first equation (78*b*), we should, in strictness, clear off fractions to obtain the rational differential equation. But the advantages of the form (78*b*) are too great to be lightly sacrificed to formal accuracy.

We have now the means of fully investigating the transmission of disturbances along the line, including the retardation to inward transmission from the dielectric into the conductors as well as the effects of the electrostatic charge. The system is a practical working one; for, the electrical variables being V and C, we are enabled to submit the line to any terminal conditions arising from the attachment of apparatus, the effect of which is fully determinable, because the differential equation of the apparatus itself is one between V and C. Both the ratio of V to C and their product are important quantities. The first is, in steady flow, a mere resistance. In variable states it becomes a complex operator of great importance in the theoretical treatment. The second is the energy current, concerning which more in the next section.

In the meantime I will briefly indicate the nature of the changes made when we go further towards a complete representation of Maxwell's electric and magnetic connections. First, as regards the small radial component of current in the conductors. The quantity s that appears in the expression for R_1'' is given by

$$-s_1^2=4\pi\mu_1k_1p,$$

μ_1 being the inductivity and k_1 the conductivity of the inner conductor, whilst p is, when we are dealing with a normal system of subsidence, a constant; thus, ϵ^{pt} is the time factor showing how it subsides, p being always negative in an electro-magnetic problem, and also always negative in an electrostatic problem, whilst in a combined electrostatic and electro-magnetic case it is either negative and real, or negative with an imaginary part, when its term must be paired with a companion to make a real oscillatorily subsiding system. Now the simplest form of terminal condition possible is $V=0$ at both ends of the line, *i.e.*, short circuits. Then

$$V=A\sin(j\pi x/l),$$

where j is any integer, represents a V system, satisfying the condition of vanishing at both ends. Let the factor of x, which is $j\pi/l$, be denoted by m. Only the first few j's are of much importance, 1, 2, 3, &c. Now, if we change the connection between s_1 and p above given to

$$s_1^2=-4\pi\mu_1k_1p+m_1^2,$$

we shall be able to take the radial component of current in the conductors into account; but the change made is usually very insignificant. There are four other cases in which we can work similarly—viz., when the line is insulated at both ends, or $C=0$; when it is insulated at either end and short circuited at the other—two cases; and when the line is closed upon itself, each conductor making a closed circuit without interposed resistances, &c. In all except the last case, when the line has no ends, the quantity VC vanishes at both ends of the line, either V or C being zero at these places, so that no energy can enter or leave the line (dielectric and two conductors). Nor can this happen in the last case. But if we join on terminal apparatus, thus making VC finite at one or both ends, the system breaks down, and we require to fall back upon the preceding.

But if we keep to the five cases mentioned, we may make a further refinement, by taking the longitudinal current in the dielectric into account, which we have previously considered negligible in comparison with the current C. We cannot do this in terms of V, which is inadequate to express the electric energy. But we may do it in terms of the electric and magnetic forces, and then obtain a full representation of Maxwell's connections, instead of an approximate. But even in this it is assumed that there is no magnetic disturbance outside the outer conducting tube or inside the inner, which there must really be, for we must have continuity of the tangential electric force, which necessitates electric force, and therefore also electric displacement and current and magnetic force, outside the outer tube, having some minute disturbing effect on the current in the conductors.

We may, however, leave these refinements to take care of themselves, and return to the V and C system of representation. The advantage of dealing with concentric tubes is due to the circularity of the lines of magnetic force, which produces considerable mathematical simplifications, as well as physical. Suppose, however, the tubes are not concentric, although the dielectric is still shut in by them. Here, clearly, to a first approximation we have merely to give changed values to the constants S and L, whilst R is unchanged. But to go further, the determination of R_1'' and R_2'' will present great difficulties. This, however, is clear: that the full L′ will have for its minimum value, approached with very rapid oscillations, L_0, such that $SL_0=v^{-2}$, where v is the speed of propagation of undissipated disturbances through the dielectric. This follows by regarding the conductors as infinitely conducting, so that there is no waste in them, when the equation of V becomes

$$\frac{d^2V}{dx^2}=\mu_2c\frac{d^2V}{dt^2}, \quad \text{or}=SL_0\frac{d^2V}{dt^2}, \quad . \quad (79b)$$

showing wave propagation with velocity v.

But if the two conductors be parallel solid wires or tubes (not concentric), and be placed at a sufficient distance from one another, the lines of magnetic force in and close round the conductors will be very nearly circles, so that we may regard R_1'' and R_2'' as known by the preceding; and we can therefore go beyond the approximate method of representation founded upon R, S, and L only. Even if we bring the conductors so close that there is considerable disturbance from the assumed state, we should still, in reckoning R_1'' and R_2'' in the same way, go a long distance in the direction required, especially in the case of iron wires, in which, by reason of the high inductivity, the magnetic retardation is so great.

The effect of leakage has not been allowed for in the preceding. The making of the necessary changes is, however,

Digitized by Google

quite an elementary matter in comparison with those connected with magnetic retardation. We require to change the form of the equation of continuity. If there be a leakage fault on an otherwise perfectly insulated line, we have the line divided into two sections, in each of which the former equations hold good; whilst at the place of the leak there is continuity of V and discontinuity of C, the current arriving at the leak on the one side exceeding that leaving it on the other by the current in the leak itself, which is the quotient of V by the resistance of the leak, if it be representable as a resistance merely. But when the leakage is widely distributed it must be allowed for in the line equations. Even in the case of leakage over the surface of the insulators of a suspended wire, the proper and rational course is to substitute continuously distributed leakage for the large number of separate leaks; which amounts to the same thing as substituting a continuous curve for a large number of short straight lines joined together so as to closely resemble the curve. The equation of continuity becomes

$$-\frac{dC}{dx} = KV + S\dot{V} \quad . \quad . \quad . \quad . \quad . \quad (80b)$$

where the fresh quantity K is the conductance, or reciprocal of the insulation resistance, per unit length of line. That is, the true current leaving the line is the sum of the former $S\dot{V}$, the condenser current, and of KV the leakage current, both of which co-operate to make the current in the line vary along its length, although in the steady state it is the leakage alone that thus operates. But as regards retardation, their effects are opposed. The setting up of the permanent state is greatly facilitated by leakage, as is most easily seen by considering the converse, viz., the subsidence of the previously set up steady state to zero when the impressed force is removed. If, then, we wish to increase the clearness of definition of current changes at the distant end of a line on which electrostatic retardation is important, we can do it by lowering the insulation resistance as far as is practicable.

(To be continued.)

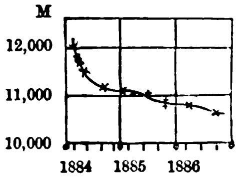
PERMANENT MAGNETS.—III. ON MAGNETIC DECAY.*

BY R. H. M. BOSANQUET, St. John's College, Oxford.

In the *Philosophical Magazine*, ser. 5, XIX. 1885, pp. 57-59, I gave an account of the decay of the magnetism of a pair of permanent magnets during some months after they were made.

Observations for H have been continued at intervals with the same pair of magnets, both in the laboratory and the non-magnetic room; incidentally a large number of determinations of the moments of these magnets have been obtained, and from these an interesting result appears to follow with considerable certainty.

The decay of the magnetism proceeds much more rapidly in summer than in winter; and in all probability the rate of decay is quicker for higher temperatures and slower for lower temperatures.



It will be remembered that Joule proved, by burying systems of magnets for several years, that the maintenance of a constant temperature did not secure the constancy of the magnetic intensity (Reprint, Vol. I., page 592), on which Joule remarks, "so that the cause of the gradual decline of power has yet to be discovered."

Regarding heat as a species of molecular agitation, it seems reasonable to expect that this agitation should act in a manner analogous to mechanical disturbances, in facilitating the decay of permanent magnetism. In fact, we know that by exposing permanent magnets to moderately high temperatures, we can destroy their magnetism altogether.

The following are the mean results of the sets of observations that have been made. The changes in the value of M are shown in the figure. It will be seen that they are much greater in summer than in winter.

N.B.—The temperatures were always noted, and the temperature-coefficients of the magnets were determined by a careful discussion. They are not large enough to produce any difference in the numbers which need be taken into account for the present purpose.

SECONDARY BATTERY PATENTS IN THE UNITED STATES.

Owing apparently to the recent introduction of the Julien battery for tram-car work upon the New York lines, the Brush Electric Company has issued the following notice:—"On May 17th, 1882, the public was cautioned against making investments in any scheme or venture based upon the claims of one Camille Alphonse Faure, relating to secondary or storage batteries or accumulators, and notice was then given that the Brush Electric Company, of Cleveland, were the rightful owners in this country of the inventions laid claim to by Faure and others, and were enforcing their rights by proceedings before the proper tribunals of this Government. Those proceedings have been pushed with diligence by the Brush people, and have been opposed and delayed in every possibl· way by the Faure interests and others for a period of four years. Decisions, however, have at last been rendered in favour of the Brush interest, and patents have been granted to it covering the entire ground claimed by the Faure people, and the Faure patent is thus rendered valueless. Twenty-seven patents, covering the field above referred to and of cognate scope, have been granted to the Brush Electric Company, and one or more of them cover all the commercial batteries that have been up to now devised. The two principal and foundation patents, which control the use of the so-called Faure storage battery, as well as the Sellon-Volckmar battery and others in this country, and supersede the patent issued to Faure, Jan. 3, 1882, numbered 252,002, are dated and numbered respectively March 2, 1886, No. 337,298, and March 2, 1886, No. 337,299. The public are again advised, as they were in 1882, of the rights of the Brush Electric Company, and that these rights will be enforced."

THE HIRE AND PURCHASE SYSTEM.

With the steady growth in the manufacture of dynamos, and an ever increasing demand for them, there has arisen a difficulty which older industries of a similar kind have wholly or partially overcome, but which is quite novel to the Electrical Engineer. We refer to the high price of his goods. Possibly the cost of material and construction may be somewhat reduced as time goes on; but not, we think, to any considerable extent. The highest scientific authorities, so far, do not favour cheap machines, and the circumstances of the last three or four years have certainly not conduced to set a higher price on the dynamo than its makers are justly entitled to. On the contrary, it is known that they have sometimes made and sold at a loss. Probably, therefore, the present prices of firms who have a good reputation will be maintained. This being so, they are confronted with precisely the same question with which agricultural implement makers and the makers of steam engines had to deal in the early days of their career, namely, how to find a market for their commodities where ready capital was not available for a large immediate expenditure.

To put the matter plainly, we will suppose that electrical plant is wanted for electric lighting or mechanical purposes by a man of good credit, or a perfectly respectable firm who may not be willing, or possibly not be able, to purchase outright with cash down. At present there is no recognised usage in the electrical engineering trade to justify any course other than sale for cash or credit—the latter method being always attended with risk. In reality, if the plant cannot be paid for it cannot be had. But this is not the case in respect to some other well-known businesses. Notably, there is the familiar hire system applicable to furniture, and, we believe, recognised by law. A similar plan, if we are not mistaken, has been for some time in vogue among the makers of steam engines, which are let out for hire on the redemption purchase system. Individuals or firms situated as above described are enabled under such provisions to obtain and employ machinery which is partly paid for, but which remains the property of the maker until the whole price is cleared off, or reverts to him on payments failing. No custom of this kind has yet been tried in the electrical engineering trade, not, at all events, to an extent which would stamp it as a usage of the trade in any court of law.

To establish this usage, in the legal sense of the word, would, we think, be of considerable service to the firms now engaged in manufacturing dynamos and other expensive electrical appliances; for without some such recognised usage there is reason to fear that property once out of the hands of the makers would be liable to seizure under an act of bankruptcy, the far-reaching and sweeping powers of which are of a most comprehensive and indiscriminate character. Nobody seems to know what trustees in bankruptcy may not seize, but as the prevailing belief is that they will seize anything, and can be made to restore only with extreme difficulty, nobody cares to run any great risk in order to challenge these powers. It is even thought that the stringent agreement customary in the case of old established hire systems would not avail where custom has not sanctioned it, the argument being that creditors are not sufficiently warned that property on the premises may be only there on hire, in cases where, unlike that of furniture for example, the custom of hiring is not common and generally known.

Now the seizure of hired property under the bankruptcy of the hirer would be very hard upon the owner, even if he had received part of the purchase instalments; but it would be vastly worse if he had only let the property on hire with or without the option of purchase. Yet to both of these contingencies the owner of electrical plant would be liable. More correctly, we should say he believes he is liable; and the belief is undoubtedly acting as a deterrent against parting with his goods without money down; and consequently preventing him doing business where otherwise he might be doing it. This is not only bad for the electrical engineer, but bad for the progress of electric lighting and electrical machiney everywhere. It is not desirable to push a business otherwise flagging by illigitimate means; but where the demand is largely increasing, and the supply only flags because of a legal technicality, any efforts to remove it out of the way are perfectly legitimate and highly desirable.

To this end we would venture to offer a few practical suggestions, the first of which is to invite correspondence on the points we have raised, namely, as to the expediency of adopting some form of the hire system, or hire-and-purchase system, to the business of electric engineering; and as to liabilities supposed to be incurred by adopting either of those systems. Some experience may have already been gained that has not come to our knowledge, and some legal opinion may have been obtained which, if made public, would be exceedingly useful. Secondly, we suggest correspondence on the question whether it would be practicable for members of the trade to combine for the purpose of making their willingness to let out machinery on hire known to the public with the view of establishing the "usage" which is wanting in this particular "trade;" and, further, whether such

Digitized by Google

a combination acting in the way suggested would have any legal effect in securing property against seizure in the event of the purchaser or hirer becoming bankrupt. Of course every contractor acting on his own responsibility will take care that his name plates and labels are affixed to his plant; and where there is risk he will retain practical possession by leaving his own *employés* in charge of it. Other precautions for immediate use will readily suggest themselves; but we think, on the whole, that the safest course will be for persons interested to act together in this matter for some time to come; and with this end in view we shall freely open our correspondence columns to any useful hints or suggestions that may reach us. The subject is not exactly a cheerful one, but in a sense it is seasonable. Christmas is the time for overhauling accounts as well as paying them, and the outlook for the coming year may be rendered more hopeful by due consideration of the subject we have here started. But be this as it may, our readers, one and all, may be assured of our hearty goodwill and best wishes for the season, and for the coming New Year.

CORRESPONDENCE.

BABBAGE'S NOTATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you kindly grant me space to ask whether any of your readers can inform me of a publication containing the system of Notation invented by Babbage. This system was, I believe, first explained in a paper read by the author before the Royal Society in 1826. As none of the public libraries in this neighbourhood have the *Proceedings* of the Society for that date, I am unable to get what I want.

The Notation is referred to in a great number of books, but so far as I am able to ascertain not the slightest explanation of the method is contained in any of Mr. Babbage's numerous works now in circulation. Perhaps some of your mathematical readers will be able to guide me.—Yours, &c.,

12, Langside-road, Govanhill, Glasgow. DAVID COOK.

INVESTIGATIONS ON THE ACTION OF SOLENOIDS ON DIFFERENTLY FORMED IRON CORES.*

There have been numerous experiments made on the mutual action between solenoids and iron cores. Of the earlier ones the most remarkable are those of Hankel. Lately we have had those of Krizik and Böttcher, in which trials have for the first time been made also with doubly conical cores. The significance of these last investigations lies especially in the fact that they are the first which have been made on the attraction between non-cylindrical iron cores and a solenoid. The results of Böttcher and Krizik, however, disagree, and it becomes of some importance to make accurate investigations on the attractions between solenoids and iron cores of other than cylindrical shape.

The most usual regulators of arc lamps can be divided into two classes: the first and greater one, where a solenoid and iron core remain essentially always in the same position relative to one another; and a second one where the iron core continually shifts its position relatively to the fixed solenoid as the carbon burns away.

In this last arrangement it appears to be desirable that the force between the solenoid and iron core should remain constant, or nearly so—a thing which is impossible in the case of a cylindrical core. It has been proposed to compensate the variation of the attraction in this case by a mechanical arrangement; but this would detract from simplicity and compactness, both special requisites for the regulator of an arc lamp. Efforts have been made on the other hand to make the action between the solenoid and its core uniform in itself, without further mechanism; and such efforts were, it seems, first made by Krizik.

Krizik made experiments both with cylindrical and doubly conical cores, and among his results were the following:—In the case of a cylinder he supposed that the maximum attraction took place when the end of the cylinder was at the middle of the length of the solenoid, and that from thence the attraction diminished to zero, and then to a negative maximum.

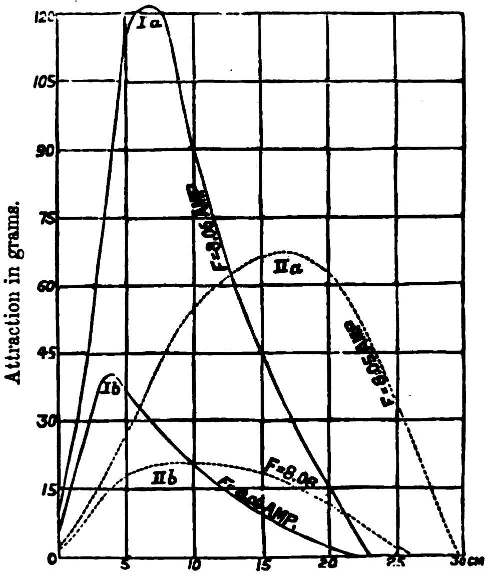
He supposed that two cones united at their bases might give uniform action within certain limits.

Böttcher declared that Krizik's results were wrong, and said that the maximum attraction did not take place when the end of the core coincided with the middle of the length of the coil, and that the action with the double cone did not differ essentially from that with a cylinder. Other investigators also have not confirmed Krizik's results.

The author then proceeds to describe his own investigations on the subject.

He first tried whether the relative lengths of the coil and the cylinder had any influence. He shortened his first-used coil to a half, then to a quarter, of its original length, and finally used one winding only; but in each case the attraction was unaffected by the relative lengths of the coil and core.

The results of the next part of his researches, which relate to the variation of attraction with relative position, are given by the curves of the diagram, in which abscissæ represent the distances of the lower end of the core under the upper end of the solenoid, whilst the ordinates represent the corresponding attraction in grams. The iron cylinder employed was 39cm. long, whilst the coil had the lengths 0·8, 3·5, and 7·0cm. Only the results for the latter two lengths of the solenoid are given in the diagram. One sees from these curves—that is, the



Lowering in centimetres.

Ia, IIa } Height of solenoid 7cm.

Ib, IIb } Height of solenoid 3·5cm.

FIG. 1.

undotted curves I*a* and I*b*—that here the maximum attraction takes place when the lower edge of the core coincides with the lower edge of the coil, and it gives accordingly for a core which is six or twelve times as long as the solenoid the same result as Böttcher found for cores which had twice and three times the length of the coil. Also the result of Hankel's investigations with a core of eight times the length of the helix agrees with these.

Hence it appears that with cores whose length is double that of the coil, or more than double, the position of maximum attraction is always nearly the same, and this is when the end of the core coincides with the end of the coil.

* Abstract from a paper by Dr. Th. Bruger, of Darmstadt, in the *Elektrotechnische Zeitschrift* for May, 1886.

Digitized by Google

Further experiments showed that the maximum point of attraction with a cylindrical core was the same for all strengths of the current, as might be expected. The two dotted curves, II*a* and II*b*, refer to experiments with a conical iron core instead of the cylindrical one.

The author's experiments in the case of a double cone confirmed what Böttcher said, namely, that the action was little different from that with a cylinder.

We may, however, regard as an improvement the introduction of a long single cone as core in the lamp regulator, for here the zero of attraction does not take place at the coincidence of the middle of the core and the middle of the solenoid, but more towards the thicker end of the core.

Arrangement and Method of the Experiments.

The following is the description of the apparatus employed, which is represented in Fig. 2 :—

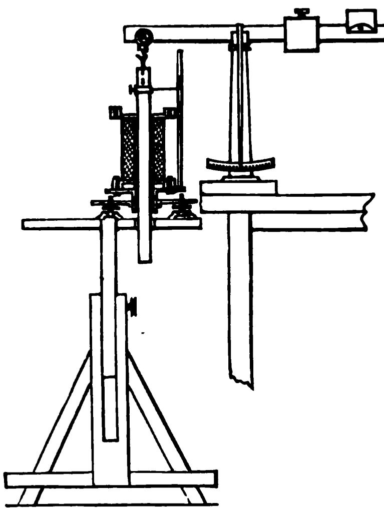


FIG. 2.

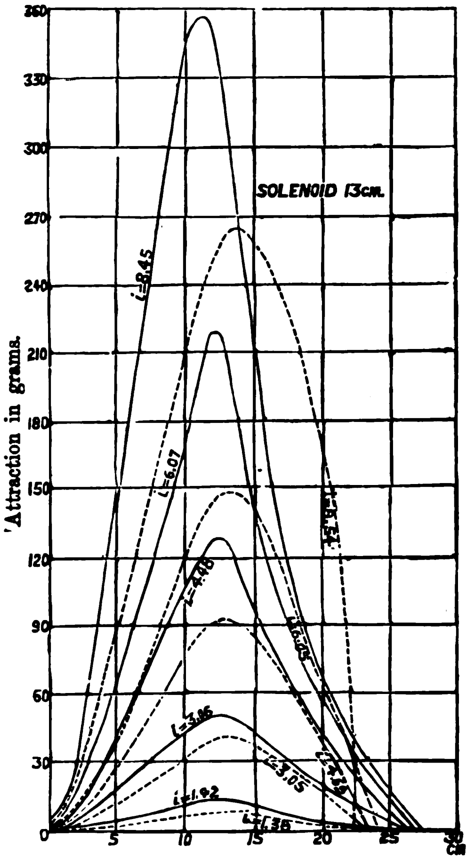
On a little wooden table with a board with a hole in it, which could be raised or lowered vertically, stood a brass plate, provided with three levelling screws, into which, again, a little removable brass table was screwed. The brass plate and the little table were also bored through in the centre, so that the iron core, hanging to the beam of a pair of scales, could conveniently pass through without touching from any slight vibration. On the brass cover was again a vertical silvered scale divided into millimetres, on which one could read the sinking of the iron core into the coil. The balance, which like the rest of the apparatus was specially fitted for the purpose, was constructed like the well known Mohr's balance. There was a weight, which could be moved along the arm and fixed in any position by means of a screw, and this was used to balance the iron core exactly when there was no attraction on it—that is, when the coil had no current in it. The attracting force of the solenoid was measured by brass weights pushed along the scale beam, which had divisions on it. The relative position of the solenoid and iron core was read off on the above mentioned scale, by means of a pointer, which could be screwed on to the core under consideration, and had edges over which the scale was viewed. The determination of the attracting force took place in the following manner :—First of all the position of the core in the coil was read off when there was no current passing, and then on closing the circuit weights were added to the longer arm, so that equilibrium was again obtained when the coil and core had the same relative position. Care had to be taken that at closing the circuit the core was not suddenly drawn down deep into the solenoid, but that the motion was at once stopped, so that its position was little altered. Otherwise a too strong magnetisation took place, and the value of the attraction for the point under consideration was too great.

Comparison of an Iron Cylinder with a Double Cone.

The cylinder was 39 cm. long and 1·5 cm. thick, whilst the somewhat shorter double cone had at its centre, or common base of the two cones, a diameter of 2 cm. and at the ends of 3 mm. The solenoid used was that of a Schuckert arc lamp. It had a height of 13 cm., and was wound with 2·6 mm. copper wire in seven layers each of 38 windings. The attraction on the two cores was determined with five different current strengths, from about 1·5 to 8 amperes. The results obtained are indicated in Fig. 3. The dotted



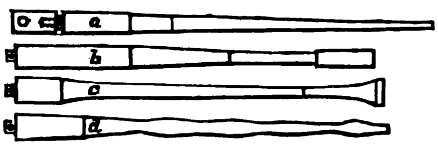
Lowering in centimetres.

FIG. 3.

lines here refer to the doubly conical, and the plain lines to the cylindrical core. A consideration of this diagram shows that a similar result to that of Böttcher was obtained. A double cone is not a core of constant attraction, and its action differs little from that of a cylinder. The points of null and maximum attraction have the same positions with both cores, and no advantage worth mentioning is obtained by the exchange of the cylinder for the double cone. The curves retain their form with different current strengths, and the two characteristic points do not shift their places.

Comparison of an Iron Cylinder with an Iron Cone.

The cylinder was the same as in the preceding experiments. The cone, provided with a cylindrical top, belonged, like the solenoid, to an arc lamp. It had the same weight as the iron cylinder, and is represented in Fig. 4*a* of a quarter the natural

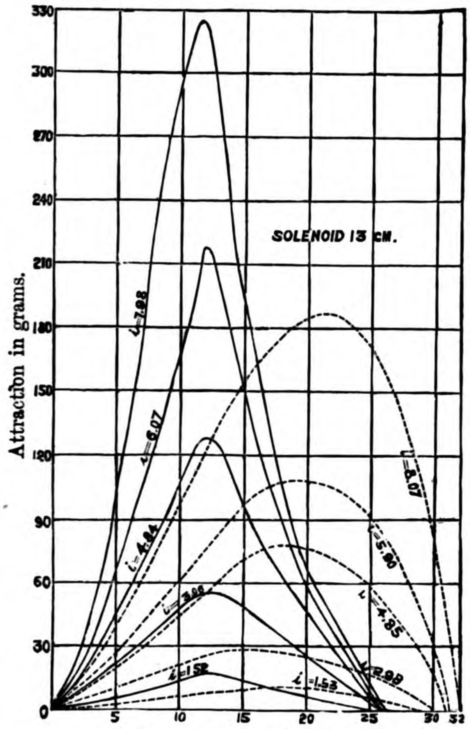


FIGS. 4*a*, 4*b*, 4*c*, 4*d*.

size. The curves given in Fig. 5 again represent the attractions with five different current strengths, the highest of which about corresponded to that actually used in the arc lamp. It can be seen that the single cone has an advantage over the cylinder, since the curve is flatter. It should be straight, and parallel to the axis of abscissæ for the attraction to be actually uniform. With the single cone there is a slight shifting of the point of maximum attraction as the current increases. It can be

Digitized by Google

seen that with increasing current strength the point of maximum attraction retreats from the under thin end of the core towards the upper thick end. The reason is to be found in the greater mass of iron at this end. The shift in the position of the null point of attraction is small compared with that of the maximum point, but it appears as if with increasing current strength it inclined to take up such a position as to occur when the centre of gravity of the cone coincided with the centre of coil.



Lowering in centimetres.
FIG. 5.

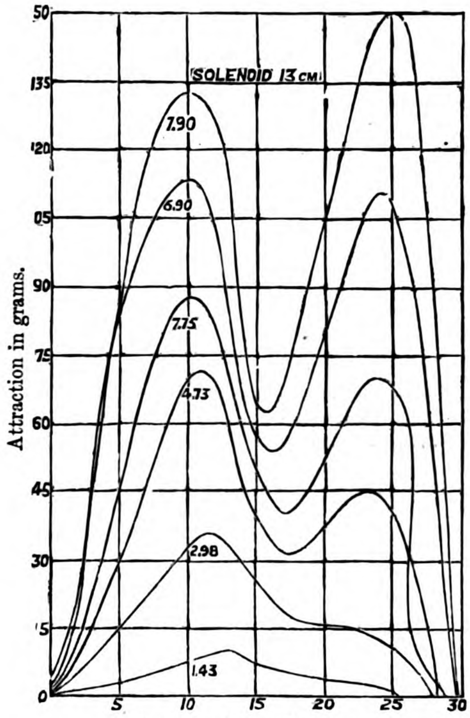
It appears from the foregoing that, though the single cone has a more constant attraction than the cylinder or double cone, this attraction is still very far from actually constant.

Experiments on a Form of Core lately proposed by Krizik.

These cores are made by adding together cylindrical and conical pieces of iron, and the attraction curves for two of them show comparatively favourable forms, in that for a distance of about 7cm. they run in a straight line parallel to the axis. The author made experiments with a core of the form shown in Fig. 4*b* (which is here shown of a quarter the real size), and the attraction curves with different current strengths are shown in Fig. 6. It can be seen that with such cores of complicated shape the whole form of the attraction curve alters with alteration of current strength. The reason is that the saturation of different parts of the core corresponds to different current strengths. With such a core, therefore, we shall have a favourable result only for near about one particular current strength. The limits between which this constant attraction occurs are very narrow, and this is still the case even for Krizik's best result with a core rounded off below in a parabolic form; for here the attraction is constant only for a distance of 7cm. Besides, this core would not suit an arc lamp regulator, because the current was too weak. In the experiments here described, the same solenoid was always employed, which was about 13cm. high. It became of interest to determine the attraction of solenoids of other dimensions on these irregular forms of core, and the core was consequently subjected to the action of two coils whose heights were the half and then the quarter of that initially employed. Here, as was the case before, the most favourable results were obtained with a current strength of 3 to 4 amperes. The whole type of curve is little altered, yet it appears as if better results might be here obtained with short coils, for the parts parallel to the axis become somewhat longer. But naturally the actual value of the attraction was diminished.

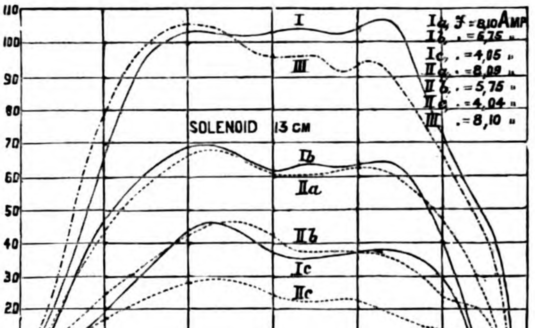
Next a core of the form shown in Fig. 4*c* was tried. This form was decided upon for theoretical reasons, and did not give very satisfactory results.

After a long course of experiments with cores of somewhat different shapes, the author finally arrived at the form shown in Fig. 4*d*, and obtained with it the plain (*i.e.*, not dotted) curves shown in Fig. 7. These curves are not straight and parallel to the axis of abscissæ; but they are more nearly



Lowering in centimetres.
FIG. 6.

so than the others for a certain distance. It might be possible to make the curve still straighter by further altering the form of the core, but the experiments are tedious. The rendering of the curve uniform is much easier for small than for large currents.



Lowering in centimetres.
FIG. 7.

The dotted curves II*a*, II*b*, II*c* refer to cores of cast iron, and curve III. to another wrought iron core of much the same shape as I., but rather lighter in weight.

The attraction with cast iron is not so great as with wrought, but the form of the curve seems to be independent of the kind of iron.

ELECTRO-PLATING WITH PALLADIUM.—*L'Electricien* states that M. A. Balle, of Besançon, has succeeded in depositing palladium upon iron and steel by electrolysis; but no details of the method are given. The coating obtained is said to be perfectly adherent, and so fine and hard that after removal from the bath no further treatment is required, and the process may be applied to finished articles.

ELECTRIC STREET CARS.

By the courtesy of the editors of the *Electrical World* of New York, we have been favoured with an advanced proof of the following paper, which was read by Mr. T. C. Martin on Dec. 7, before the American Institute of Electrical Engineers :—

"The struggle for supremacy in this field of occupation may fairly be said to have narrowed itself down to three competitors—the horse, the cable, and the electric motor. Steam used directly is, it seems to me, viewed with more and more disfavour as the years go by, and has within city limits come to be considered very much in the light of a nuisance. The lowest cost of operation per steam motor per day, in usual service, that I have seen quoted authoritatively is $8.50 and $7. But even if steam were cheap, there are grave objections on the score of noise, smell, and dirt. The mere fact that steam locomotives have been in successful use 50 years, but are still denied employment on the streets, tells its own story as to public opinion. To some of us the banishment of steam even from the tracks of elevated roads seems a matter of but a few years. As for gas, soda and compressed air motors, I am not aware that they offer any points of superiority over steam for the specific purpose under discussion.

"Coming to horses, we find that in spite of their universal use and their faithful performance of duty, they inspire a discontent anything but complimentary, yet hardly to be wondered at. The statistics of horse cars are important and interesting, and deserve our attention as covering the sphere within which the electric motor will operate. There are, according to the latest returns available for this year, about 625 street railways of all kinds in the United States and Canada. Taking of these 408 horse roads giving full and trustworthy figures, I find that they run 17,331 cars and employ 85,888 horses. If at the same ratio we took all the horse roads, upwards of 500, we should arrive at a result of not far short of 25,000 cars and 150,000 horses, a total that probably comes very near the actuality. Taking the other figures, which I have tested by three sources of information, it appears that the horse car lines are maintaining a proportion of at least five horses to each car. But that is inclusive, and making a reasonable allowance for the use of different cars for winter and summer, and for idle cars, as well as for 'doubling-up' in heavy snows, a result is shown of at least eight to ten horses per car.

"The costliness of horses may be arrived at in yet other ways, by the use of comparative figures. Mr. T. C. Robins, of Baltimore, a street car expert, gives the average cost of horse car per day at $6.50. I have had the same figures given me for Brooklyn and Philadelphia. Mr. C. B. Holmes, of the Chicago Cable Railway, who has had great experience with horse service, says that the expense per car mile by the cable system is 10 to 11 cents, as compared with 20 to 25 cents per mile when employing horses. On a daily run per car of 50 miles, that would be at least $12 per day with horse traction, and half as much for cable. Moreover, there are the great extent of valuable land required for huge stables and the heavy depreciation of stock. Few occupations are more exhausting to horses than street car traction, and the average railroad life of a horse is but three to five years. In other words, out of 100,000 horses, at least 20,000 every year die or become useless for their work, and drag out the remainder of their existence in other occupations.

"The cable has already made its way into use on a large number of street railways doing a heavy business, and is, it must frankly be admitted, a vast improvement on old methods. It has enabled those roads to handle a traffic that was utterly beyond their capacity before. It has accelerated speed, has lessened accidents, has given the streets a cleaner look, has, it would seem, cut down expense, and has certainly raised the value of property wherever put in. But I doubt seriously whether in view of the enormous first cost of the cable system and the excessive waste of power, it will make very rapid strides, especially when subjected to the rivalry of electric motors. At the recent street car convention, the new cable roads at Kansas City were presented for favourable notice, and as they were evidently considered good specimens, let us accept the figures. The Metropolitan road will cost $50,000 per mile of single track, and I observe that it is claimed with regard to the Philadelphia system that the track there could now be duplicated at about the same cost. The Kansas City Cable Company gives some interesting results of a test of its engines and machinery, from which I gather that with a total of 159·7 horse-power, no less than 119·06 horse-power was required for the cable machinery, leaving only 40·64 horse-power for cars and passengers. In other words, just 25 per cent. was available for actual traffic. This waste will strike electricians familiar with the high efficiency of dynamos and their transmission of power as extraordinary. But it is confirmed by a statement from Mr. C. B. Holmes, of Chicago, who says that his cable railway required for ordinary operation engines of 477 horse-power ; that it took 389 horse-power to move the cable and machinery, and that 88 horse-power, or only 18½ per cent., was used for the propulsion of the cars at nine miles an hour. Mr. W. W. Hanscom, in a careful review of the conditions applying to the cable lines of San Francisco, gives a total daily average percentage on the seven roads of 68 per cent. of power for moving the cable, and 32 per cent. for the cars and passengers. Two miles of new double-track in San Francisco, fully equipped, have just cost $400,000.

"I do not know that these figures call for comment, as those presented later on in regard to electricity will serve for purposes of comparison. But they may be supplemented by one or two observations. It is evident that there is an objectionable rigidity in the cable system, and that it has narrow limits of applicability. A cable road, of whatever kind, needs a very large patronage. Mr. P. A. B. Widener, well known in connection with Philadelphia street railways, said last year :—'To maintain a cable road you must have a certain amount of business in order to be self-supporting. It costs as much to run the cable for half a dozen cars as for half a hundred. Small roads, or feeders to the main line, are run more cheaply by horses.' It will be remembered that great trouble was experienced in Philadelphia in rendering the cable system there operative last year. The assertion is made by those who should know that 12 miles, costing between $40,000 and $50,000 a mile, required $250,000 in repairs and renovation inside the twelve months.

"We New Yorkers have learned that the cables wear out quickly, besides being ceaselessly noisy and requiring a conduit that must have such depth as to become an unhealthy drain or sewer.

"We reach now, in the due course of our survey, the use of electricity as compared with horses or cables. You will, I believe, bear me out when I say that the confidence of electricians in the ability of electrical means to propel street cars is as strong as it could possibly be, and is moreover based on no small amount of work and experience. I might affirm that the general introduction of electric motors is now largely a question of coal bills. I might affirm that it has more and more resolved itself into a question of mechanics ; and in both statements I should have your concurrence. I might broadly state that in Europe, where a large number of electric roads exist already, they are paying well and multiplying ; and that such roads in this country had, some months ago, carried altogether over a million passengers, or a daily traffic of 3,000 passengers for a full running year, without any recorded injury to a single patron, while several new roads have of late gone into successful operation. But at the risk of covering much ground with which you are familiar, I shall venture to give an outline of some of the methods by which electricity is applied to street-car service, as well as some of the data establishing its claim to superiority. I do not know of any point on which a fair comparison need be shirked ; I do not know of any difficulty that can tame the infinite variety of our electric art, and as this society has never hitherto had the subject before it, I am encouraged to go a little into detail.

"We have, in using electricity for street cars, the option of so many methods that the very flexibility of the application becomes a recommendation. We shall, perhaps, best spend our time in considering three or four of the leading methods, with incidental reference to the peculiarities of individual cases in each. I propose to take the third rail system, the overhead system, the conduit system, and the storage system, and, without any intention of invidious discrimination, to pick out, for the exemplification of each, some of the roads and cars that have been running or can be seen and tested.

"Let us begin with the third rail system. The Daft road at Baltimore, now in its second year, has been so often described that full details are not here necessary, but it furnishes some interesting figures. The cost of electric power there against horse-power at $6.50 per car has been $4 per car per day, with an increase for the year of 83,986 passengers. Mr. T. C. Robbins reported as follows to the street car convention :—'It was started on a purely commercial basis, as a purely commercial transaction, and has continued, and is now being extended, simply because it has proved its right to stay by the performance, which leaves little to be desired.' The largest item in the expenses at Baltimore is coal at $3.50 a ton. Another third railroad, the Highland at Detroit, on which there are none of the grades and curves that rendered the Baltimore road expensive as to fuel, is in very successful operation. Like the Baltimore road, it has a wheel for making contact ; but, unlike it has the third rail neatly sunken between planks. It runs out of the city for three miles. The car in use is the same as those on Broadway, this city. Mr. Frank Fisher, whose motor is used, informs me that on a recent Sunday, on a thirteen hour schedule, the road carried 5,500 passengers. The coal consumption was a little over 400lb. The coal—screenings—cost $1.25 a ton. The success has been so great as to lead to a development of plans matured for the increase of the surface there and on a local road to be begun in the spring.

"You will agree with me, I think, that third rail systems must be limited to a low electromotive force, and to surburban or rural districts. Even there they have a large opportunity.

"Coming to the overhead conductor systems, the Van Depoele roads form an important group. These roads are now in operation at Detroit, Port Huron, Mich., Windsor, Can., Appleton, Wis., Montgomery, Ala., and Scranton, Pa. Mr. Van Depoele suspends his feeding conductor by side poles, or, as at Appleton and Scranton, has double wires, corresponding to the track, but immediately above it at a height of 18 or 20ft. The little Windsor road, two miles long, with two cars, started in June, 1885, has paid for itself. The Appleton-road, with five cars, is the first in this country run by water-power, depending, and with great success, upon a pair of turbines that will develop 100 horse-power, and are now driving a 60 horse-power dynamo. The Montgomery-road is notable as being a complete city system, including ten miles of track. The Scranton-road that started last week has two features of special interest. One is that in a city of about 50,000 or 60,000 inhabitants the use of the overhead conductor is allowed. Another is that the line is operated from the electric light station. The road is 2½ miles long, with 12 grades, mostly over 6 per cent. There are already in use two heavy Pullman cars, running at a speed of from 4 to 15 miles an hour. The current is conveyed by a conductor $\frac{3}{10}$ of an inch in diameter, the rails forming the return. A traveller with rollers and a flexible cable passes the current to the motor, which, it is worthy of notice, stands upon the front platform in sight of the driver. The electric light station is well satisfied with only $9 a day for running the 60 horse-power generator, and it is evident, therefore, that an increase of rolling stock will involve very little increase in cost of power. Here is a hint by which electric light men nearly everywhere might profit.

"The overhead bare conductor systems are also restricted to currents of low electromotive force. But they, as well as the third rail systems, do work it is impossible to perform remuneratively by cable, and which would often be beyond the range of horse or mule power on either philanthropic or business principles. Provided permission is obtainable for running the wires, the overhead conductor system seems cheapest, if not best, for cities up to at least 50,000 population. I believe a double overhead conductor system well built should cost from $1,500 to $2,000 per mile. The single conductor is, of course, much cheaper.

"There are in the United States about 40 cities with population above 50,000. In almost every one of these it would be necessary to resort to the electric conduit system, third on our list, unless the storage system be tried, or a combination of the two. At the present time, the outlook for electric railways with conduited mains is very favourable.

"The first exemplification of a conduit system in this country was given by the Bentley-Knight Electric Railway Company, in 1885, at Cleveland."

[In order to save space we omit the description of this system, which we have recently dealt with at length.—Ed. *E.*]

"The company makes a completely equipped steel-framed truck, with motor, &c., upon which can be placed any car body. These have a wheel base of 6ft,, a standard gauge of 4ft. 8½in., and can be used on curves with a radius of 45ft. A motor of the Gramme type is used under the car. For long distances the motors are in series, with current constant; for short distances, the motors are put in multiple arc, and a new form of resistance is used. Such are the main features of the system. Of its eminent practicability there should be no doubt. The question again is one of expense, and I therefore give transcripts furnished me by Mr. R. W. Blackwell, of actual estimates submitted quite recently and now under consideration. The first is for the equipment of existing street railways in the City of New York, 3 miles 1,440ft., double track, minimum headway 1½ minutes, average speed seven miles per hour, running 24 hours per day, very heavy traffic, maximum grade 3 in 100.

"*Construction and Equipment.*—Conduit and conductors, 34,560ft., at $3, $103,680; motor trucks, 37 at $12.00, $44,400; 50 horse-power dynamos, 12 at $2,500, $30,000; steam power plant complete, $27,750; foundation, $5,000; engineering, $3,000 —$213,830.

"*Annual Expense.*—Coal, 14 tons per day, at $3, $15,330; engineer and assistant, at $2.50 and $2 per day, $1,642.50; firemen, 3 at $1.50 per day, $1,642.50; machinists, 2 at $2 per day, $1,460; total rnnning expenses, $20,075. To which should be added interest on construction cost ($213,830) at 6 per cent., $12,829.80; and also depreciation of plant at 3 per cent., $6,414.90; total expense and charges, $39,319.70.

"The second is for a down town cross-town road in the city of New York, greatest grade 1 in 12, double track; 12,660ft. conduit (extra heavy), at $4, $50,640; 20 motor trucks complete, at $1,200, $24,000; six 50 horse-power dynamos, at $2,500, $15,000; steam plant complete, $20,000; foundation, $2,000; engineering, $2,500 —$114,140.

"Of course, I do not present these figures as those upon which all authorities are agreed, but they have their value as being bids on actual work.

"In the conduit system of Mr. W. M. Schlesinger, in use for four months past by the Union Electric Company at Philadelphia, with a car running 9¼ miles an hour, the motors are intended to work in multiple arc.

"There are other conduit systems, among which I might mention the Van Depoele used at Toronto, I believe, in 1884. In the cable system, with its costly conduits, the available power for the cars and passengers reaches only about 25 per cent., in the electric conduit system, requiring for generators, conduit, and conductors, &c., but half the outlay necessary on cable system, the net return of power reaches at the minimum from 50 to 60 per cent. Mr. G. W. Mansfield, who has had considerable experience with the Daft Company, puts it as being at least 56 per cent. I note, too, that with the use of the Holroyd-Smith conduit system the Blackpool road, England, has reported earnings of $1,735 in a week, with a total expense account of $225, running 2,760 miles and carrying 44,306 passengers.

"A distinguishing feature of the conduit system is that it is the only one with which high potentials can be employed on the streets. With it, also, the power stations can be placed near ample water supply or where rents are low, or can each be given a section of road to operate.

"I approach the next and last system on our list, that of storage, with some degree of nervousness. In more than one quarter the man who comes out with a kind word for the secondary battery is set down as either a knave or a fool. I cannot see why he should be regarded as either, although he may perhaps be more than ordinarily sanguine and hopeful. I understand that storage is to be extensively used at an early date by the North Metropolitan Tramway Company in London. At Antwerp, in 1885, after six months' competition with four other cars using either steam or compressed air, the Julien electric storage car took the first prize, awarded by a jury of well-known experts. There were in all twenty-three points of comparison. The Julien car has since been tried in Hamburg, and another has been in operation on the Eighth Avenue line in this city. The question is as to the cost of maintenance of the cars and the furnishing of motive power. It will be admitted that there are advantages in having each car an independent unit, offsetting the disadvantage of carrying the dead weight of batteries; and that single cars on any road can be taken in hand for change, so that existing rolling stock can be progressively adapted to the new conditions. This involves a smaller initial outlay, and gives opportunity to train the present force in its unfamiliar though simple duties. Now, regarding first cost—I have never seen any figures as to the expense of an equipment of a car with storage batteries. It has been said that two sets for an ordinary street car would cost about $1,500. That seems high. The Julien Company states that the cost of the horses for a car more than covers the initial outlay of the change, and I believe the firm estimate is also made by the company of a total daily running expense of not to exceed $5 per car in cities on heavy traffic. As to life of the batteries, those in the Hamburg Julien car have now been in daily use since April, and they show a return of 71 per cent. of the power with which they are charged. The car is running on regular daily service. In respect to American storage batteries, it may be mentioned that the Electrical Accumulator Company, whose officers have a high standing in electrical circles, guarantees two years' life for its new battery and an 80 per cent. return of power.

"Putting it broadly, the storage system, in spite of its various conversions of energy, has a superiority of at least 25 per cent. over cables. Some of you will put it far higher, but as I have said, in the absence of the data of prolonged work, I prefer to put it low.

"I think we shall see a number of efforts shortly made in the direction of using secondary batteries for regular work on street cars, and the results will merit our most careful study. There are, moreover, some ingenious propositions for combining the conduit and storage systems, so as to enjoy the benefits of both. Mr. J. M. Pendleton has described a plan of his of this nature, and Mr. Elias Ries, of Baltimore, has also carefully elaborated such a system, in which storage plays an important part.

"Here, then, illustrated in a variety of ways and by numerous examples, we have a comparison of electricity with other power for propelling street cars, and an idea is given, very imperfectly, of the wide range of choice that electricity itself offers as to methods and means. Much of what has been said has its direct and favourable bearing on elevated railway traction, as well as on that for underground railways, but the time will not permit me to pursue the subject any further. Many points of discussion arise as to the connection of the car axles with the motor; the use of independent motor cars or of motors on the passenger cars; the types of motors and of conduits or conductors; the potential that is safe under certain conditions; the methods of regulating motor speed; the use of resistances; but all these and others I may leave to you, many of whom are doing practical and creditable work in this field, and who by thus 'hitching your waggon to a star,' have

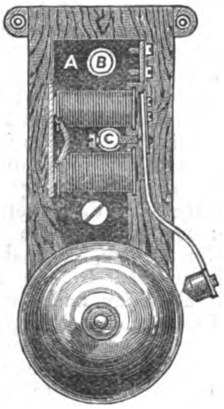
Digitized by Google

shown that street cars, if run by electricity, may yet be brought up to the most advanced notions of humanity, comfort, convenience, and economy."

ELECTRIC BELLS.

In the articles contributed to this journal six years ago by Mr. Walker Moseley, he described a short circuiting electric bell which he stated he had made and fitted up exclusively in all the installations of electric bells carried out by him since 1873. In spite of the special advantages offered by such bells, the great majority of electric bells continued to be made of the old type, which was first known and for a long time called the "French trembling bell." It was generally alleged that the action of the bell hammer in Mr. Moseley's bells was not so good as in the old sort. This was practically correct, and the only question was whether the other obvious advantages outweighed the one disadvantage. Mr. Moseley gave reasons for concluding that they did, but he has since found that the defect can be obviated, and he designed and patented an improvement last August which is now introduced into the trade.

In Mr. Moseley's former design the contact made by the armature with the short-circuiting spring was effected between the electro-magnet and the bell hammer, as close to the electro-magnet as was practicable. In the new improvement this is done—as will be seen in the illustration—between the two bobbins of the electro-magnet, and instead of the armature making contact against a spring, the spring is attached to the armature and makes contact with the end of the screw in the terminal C.



The spring usually made solely to carry the armature is continued along the back of the armature as far as the screw, and furnished the necessary spring contact with the said terminal, a hole being made through the armature to allow the end of the screw to touch the spring through the said hole. The short-circuiting terminal C is insulated from the iron base A. The terminal B is also insulated from the iron base A, but B and C are metallically connected together under the base A. One end of the wire on the electro-magnet is connected to the iron base, the other end is connected to the terminal C. Hence it will be seen that when a current is sent through the electro-magnet it will attract the armature, until the armature spring touches the end of the screw which allows the current to pass directly through the terminal B, thus cutting out the electro-magnet.

The impetus of the armature causes it to strike sharply against the ends of the electro-magnet, and propels the bell hammer against the bell, the spring on the armature effects a sharp repulsion, and when the contact-making spring leaves the contact the electro-magnet repeats its attraction as before. Although the action described is so contrary to that in the old kind of bell, the effect is apparently quite as forcible. In this form of bell there seems little chance of failure through oxidised or dirty contact with the "make and break" spring; and a service of bells may be included in one circuit. When used with indicators, as the electro-magnet is cut out the indicator is actuated by the full current, and is less likely to fail than in the old form.

The bell from which our illustration is drawn was made by Mr. Lewis, 37, New Oxford-street.

Electrification of Ice by Water Friction.—In some recent experiments by L. Sohncke a jet of water was caused to play against a sheet of ice at a certain angle. It was then found that the lower part of the jet was electrically positive to the water which had just struck the ice. In most cases water becomes positively electrified by friction with a solid. The author considers that his results are opposed to Edlund's theory, in which the usual + electrification is ascribed to a straining of the ether caused by the forward motion of the stream of liquid. Tin, steel, and glass, when rubbed upon ice, produce a + charge in the latter.

GLOW LAMPS, THEIR USE AND MANUFACTURE.

BY MAJOR-GENERAL C. E. WEBBER, R.E., C.B.

(Concluded from page 132.)

Users of glow lamps will be interested in the table shown, which is an average of several tests of the lamps of two or three makers :—

Mean current and candle-power of two long-lived 100-volt 17 candle-power lamps of different makers, run at 100 volts, and tested every 100 hours.

		Current	C.-P.
Initial current		·63 a	18·5*
After	100 hours	·65 a	18·8
,,	200 ,,	·65 a	20·7
,,	300 ,,	·65 a	18·5

* 3·4 watts per C.-P. † 5 watts per C.-P.

This gives a little history of the changes of the filament during its life. The tale told may be summarised as follows :—That during the first 200 hours the resistance decreases slightly, with consequent increasing brilliancy. These conditions remain nearly stationary for the next 500 hours. After that they alter perceptibly, increasing in resistance and decreasing in brilliancy in a progressive ratio. But it must not be forgotten that the increase in resistance of the filament is not the sole cause of the loss of light. As the filament ages, its original smooth surface roughens, and is consequently increased in area in larger proportions than it would naturally be decreased by the loss of bulk. The larger surface requires more current, whereas the increased resistance is gradually reducing the supply. Another cause of the loss of light is due to the blackening of the glass by a carbonaceous deposit, which also increases with age. This latter loss in 1,000 hours' consumption amounts, in a good lamp, to 15 per cent. This clouding over of the lamp bulb is due to an internal deposit due to the disintegration of the material, either of the wire mount or of the filament.

Dr. Fleming gave the Physical Society in 1883 and 1885 a description of some curious phenomena incidental to this aspect of the use of glow lamps. It is sufficient for our purpose to mention the cause and the effect. As time goes on in the life of a glow lamp a smoky deposit is apparently inevitable; but, quoting Dr. Fleming, "In normal use, when the lamp is not being pressed beyond the E.M.F. at which it is intended to be used, there is a general evaporation of carbon going on from all parts of the loop." His experiments tended to show that when an excessive temperature is given to the filament by a higher E.M.F., the molecules are projected with violence against the glass, causing by the more rapid disintegration an earlier obscuration of the globe than should arise under normal conditions of consumption. The rate at which the clouding takes place is rapid in the case of some defective filaments. But as a rule makers have conquered this difficulty, and it takes place under conditions which are preventible. The loss of light is very slight, and the appearance of a clouded lamp by daylight is, I think, its most objectionable feature.

Any user of glow lamps on his own installation will find, when he replaces old ones by new, that the latter will give more light, so that if he introduces a new lamp to replace one which has been broken at a period when most of the lamps are, say, 900 hours old, he will perceive a difference of about two or three candles if he uses 17 candle-power lamps. If the old lamps are, say, 1,700 hours of age, he may find a difference of seven or eight candles. As the current is not economised in proportion to the loss of light, he should recollect that a point may be reached when, by continuing the use of old lamps, there arises an important waste of power. Hence the public should judge of the efficiency of lamps outside certain limits more by their constancy of candle-power rather than by their length of life. Thus the best lamp is that which lives the longest with least variation of light.

Next we may consider the test for vacuum, which in a laboratory can be made with the induction coil as already mentioned by the following test: Hold the lamp in one hand, and bring the leading-in wires in proximity with the pole of a high potential induction coil. If the vacuum is bad, a considerable glow is visible inside the bulb; if good, the glow decreases, and will be evidenced by the length of the spark between the coil and the wires, so as to be almost invisible, and the spark outside is very faint and short. The vacuum test may also be made by the measurement of heat, to which a lamp burning for a given time will raise a given volume of water in which it is immersed; but this test has one defect.

Another, but a rougher test, is one which is made by sealing off the lamp with a short length of the vacuum tube attached, and then cutting or breaking its end under mercury, when a bubble denoting the presence of air if it exists will be detected as soon as the mercury has risen into the bulb. The users may make an approximately good test, by observing the presence of luminosity when a lamp is rubbed with the fur of a cat's skin in the dark, or by the touch. The temperature of the external surface of the bulb after it has been alight an hour or so, will show undue heating which will signify the existence of a bad vacuum. The scientific test of the candle-power of these lamps involves us in the form of photometer to be used, and above all the standard of light. The latter is a question which is

Digitized by Google

still under the consideration of a committee of the British Association. It appears to me that it is not much nearer decision than it was when brought before the Congress of Electricians, at Paris, in 1882, when the Carcel lamp and the candle still had their supporters, but there may be members of the committee present who can enlighten us thereon. For manufacturing purposes it is the practice, as I have shown is done by Dr. Fleming, to use standard glow lamps, which are frequently renewed before they have time to deteriorate. These standards are obtained by photometric comparison with flames or sections of flames of known value ; ultimately referable to an average of a series of tests with the standard sperm candle. But when it comes to competition tests between the lamps of various makers, that which is most relied on is the life test, for although that test is also a trial of the carbon it is now generally understood that most fairly well constituted filaments will live in a really good vacuum. To consumers the life test is a matter of economy. They can easily be brought to understand that if their lamps are used with a higher E.M.F. than that for which they were made,

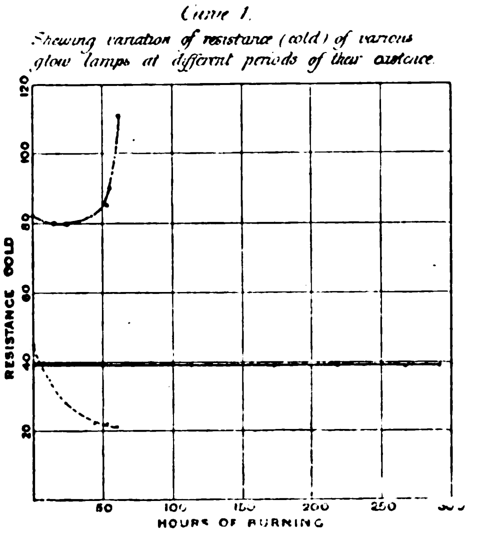

FIG. 5.

over-incandescence takes place, as well as the "clouding" already referred to. This is commonly called "overrunning" lamps, and it is very easily brought about by want of arrangement at the source of the current to secure regulation of the pressure. Often the purchaser of lamps condemns them for their short life, not knowing that all along it is his own fault, and that through frequent over-incandescence his eye has lost the power to judge, even approximately, of the candle-power he is extracting from them. It is not to be expected that he should have a photometer in his house to check this, but it is not too much to require him to have a voltmeter at a point where he may occasionally test for himself, whether the potential between his mains is dangerous to the endurance of the filaments in his lamps. If, however, his lamps behave as those did as shown in the table already mentioned, he should observe his voltmeter with the view to underrun them in adolescence, so that a healthy maturity and vigorous old age may follow. There are those present to-night, I believe, who can give the audience very interesting information on these matters.

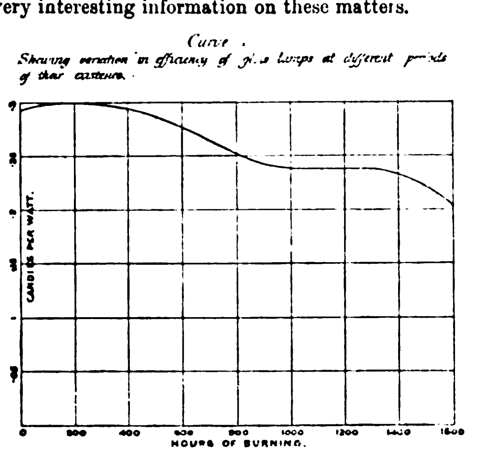

FIG. 6.—(We are indebted to the Editor of the Society of Arts *Journal* for these and the previous illustrations.)

In some lamps defective cementation of the filament to the wire mount, shows itself after a short life, by a giving way or a fracture at that point ; but no eye-test can, beforehand, detect the liability to this fault. It is still that there is a greater tendency to give way at the junction with the negative metal pole, and from this it has been suggested that when alternate currents are used, their liability to failure would be modified. It will be very instructive if some one of my audience can enlighten us this evening as to the effect on filaments by the use of alternating currents.

Time does not allow of my touching on several points of interest in connection with glow lamps, brought before electricians in late years by Mr. Wilhelm Siemens, of Berlin, by Crouto, of Milan, and by Bernstein in this country. I trust my audience will realise that my object this evening has not been to enter on too technical or debateable ground, but rather to engage their interest in the subject from its industrial point of view ; and that they will also look with approval on my abstention from touching on the patent and legal part of the question, which has so long been, and still is, a matter of controversy.

Major-General Webber requests that the following corrections may be made in his paper on "Glow Lamps":—Instead of "no further precautions are necessary," read *no further precautions to prevent arcing are really necessary.* Instead of "which unreasoningly insulates the wire which need not be in a state of electrical tension, as well as that which is always ready to discharge," read *which unreasoningly insulates that conductor which need not be in the same state of electrical tension as that which is always ready to discharge into it.*

SOME EXPERIMENTS ON SECONDARY CELLS.*

BY JAMES SWINBURNE.

This paper is a very condensed account of a large number of experiments made in the spring of 1883.

About four years ago Mr. Norman Cookson, of the well-known firm of lead manufacturers in Newcastle, brought out a process for making lead in the form of fine fibre or hair. Mr. Cookson's method is this :—The lead is melted in a pot, which is raised some feet from the ground ; from the melting-pot is a tube which leads down some six feet, and ends in a rose like that used on a garden watering can. The fall tube is kept hot throughout its length, so that when the lead is melted in the pot it is not solidified in the pipe. The melted lead then flows through the fine holes in little jets, and these jets solidify in the air, and fall in a tangled mass like lead moss. Some care has to be taken to keep the lead in the pot, and in the tube at the right temperature; but this is the only difficulty, and the whole cost of the lead hair is not more than two shillings per ton above that of pig lead.

Those who were working at secondary batteries this time four years ago will remember that most people had the idea that the great thing to be aimed at was a very large surface. Mr. Cookson's invention, therefore, seemed most valuable, and he set to work with the energy which is his characteristic, especially when working at something new. Mr. Cookson made up a dozen large cells, which he sent to Mr. Jameson, the inventor of the coke process, who was then working at an incandescent lamp. Some of the lead hair was made up into little cells, and tried in various ways by Prof. Herschel, of Newcastle. Prof. Herschel published some account of his work in *Nature*. Mr. Cookson also made arrangements with the writer to go into the question of secondary batteries. The theory that large surface of lead was necessary gave way when the question of local action was more fully studied ; but after all it seems to be near the truth.

Some reason may be demanded for bringing before this Society the account of experiments which were made so long ago. Many of them have been made again since, and many are of no use at all ; but, on the other hand, there are a number which are still new, and the next best thing to knowing what to do is knowing what not to do. We made altogether more than three hundred different cells ; but, to prevent this paper running to too great a length, only a few of them are described.

Cells with Hair Lead.—The first were Mr. Cookson's large cells. These had four plates ; each plate was about 8in. by 10in. by 1in., and consisted of a sort of cage of sheet lead with holes in each side. The lead was joined by burning, no solder being used. The inside of the cage was filled with lead hair, a lead wire being arranged zig-zag through it, and burnt to the cage. Each plate was sewn in flannel. A battery of twelve of these cells was sent to Mr. Jameson to be charged. They came back to the lead works without any particulars as to what had been done with them. We therefore coupled them up with dynamo, and charged them in what appeared to be the opposite direction. They had 12 amperes through them for about seven hours a day for no less than five months, and even after three months gas was coming off the reduced plate only. The cells seem to have had enormous capacity, and must originally have been charged in the other direction. After three months the reduced plate gave off gas, but the peroxide plates went on charging for the whole five months. We did not try running them down to see what charge they really had, as other experiments which were going on at the same time led us to suppose that the local action would render them useless. Probably the surface of these plates was so large that the local action formed enough sulphate of lead during the night to utilise the current during the whole of the next day in oxidising it. At the end of the five months the flannel round the plates was not spoilt. This seems to show that it is not the acid that spoils the flannel in the Faure cells, but the oxidation due to the contact of peroxide of lead. Some experiments on organic substances with oxidising agents will be described presently.

The first difficulty to be overcome with the Cookson lead hair was making good electrical connection with the support. Various methods of soldering were tried, but the little wires of lead were melted off whenever it was tried to burn them to the back. Solder with a flux of caustic soda ran along the fibres too much. Various methods of connecting the fibres by pressure were tried. The material was woven into loose mats, and these were passed under large rollers. Every degree of density could be obtained in this way. Though the metal was clean, and appeared to stick together at first, it did not adhere as strongly as might have been expected.

* Paper read, Nov. 25, 1886, before the Society of Telegraph-Engineers and Electricians.

The chief fault of the lead hair seemed to be the vice of local action. In those days local action was not so well understood as now. The theory seems to be this:—If lead and peroxide of lead are electrically connected, and any of the surface of the lead is exposed to the acid, that part of the surface is attacked, and a thin film of lead sulphate is formed which protects the surface from further corrosion. The lead is then in contact with the peroxide at some points, and with lead sulphate at other points, but is not touched by the acid anywhere. If the cell is charged further, the film of lead sulphate is oxidised into peroxide, so that the plate again consists of lead and peroxide of lead only. As the peroxide formed from a given quantity of lead sulphate occupies much less room, a small portion of the surface of the plate is again exposed, but is immediately coated with a film of peroxide; the result is that the whole surface of the plate is protected. The least movement seems to expose some of the surface of the lead to the acid. The lead can thus be protected by anything that prevents its contact with the acid. For local action to take place some of the lead must be exposed to the acid. If, while a cell is charging, a clean surface be made on the peroxide plate it will immediately be covered with a thin film of peroxide, which will protect the plate from further attacks. If, on the other hand, the dynamo is disconnected and a clean surface then exposed, it will be immediately covered with a film of sulphate which will protect the plate. Thus the plate may be protected either by sulphate or peroxide. When the lead of a plate is converted into peroxide the plate is being charged. When the lead is converted into sulphate local action is going on. In the large Cookson cells the fibres of lead were converted into peroxide during the day by charging, and more lead was converted into sulphate during the night by local action; so that it was unnecessary to reverse the batteries to secure more rapid formation, the formation being already rapid enough. Mr. Crompton told me this summer that he found that cells were practically indestructible if not discharged too much, and this seems to be the grand secret of successful work with secondary batteries. Messrs. Drake and Gorham mentioned the same thing in their paper read at the British Association this autumn. Either the peroxide of lead is so porous that it never quite protects the plate, or it is disturbed by small bubbles formed in the coating; for if a current is passed continually in one direction a lead plate is eaten into, as may be seen in a water resistance with lead electrodes—the oxidised plate seemingly does go on forming. In the lead hair cells the surface exposed was so enormous that a very slight formation was enough to demand a very large supply of electrical energy, so that the cells seemed to run down as fast as they were charged. No doubt the fault was that the fibres of lead used were rather too fine; if we had used much thicker lead wire we should have probably made a very good battery. Several plates were tried with hair lead, red lead, litharge, &c., but our ideas as to the validity of Faure's patent were not quite what they are now, so comparatively little was done in that direction.

Secondary cells are, however, tedious things to experiment upon. It may take a year or so to see what a cell is going to do. The best method is to keep several sets of experiments going on at the same time.

For the sake of conciseness some of each class will be given, arranged in groups.

Quick-forming.—Cells were made with lead hair in a solution of sodium chloride; the anode was quickly attacked, but the coating was not adherent, and came off in clouds; black clouds, presumably of finely-divided lead, came off the other plate.

Lead hair and potassium bichromate: seemed to oxidise well.

Lead hair and potassium sulphate: no very marked result.

Amalgamated lead in dilute sulphuric acid: the peroxide formed had little stiction or power of adherence, and kept peeling off and exposing the bright amalgamated surface; this happened especially on reducing.

The object aimed at was to get an electrolyte which partly dissolved the plate; the idea being that an action like that of which advantage is taken in the manufacture of white lead might be used in the quick formation of battery plates.

Lead in solution of sodium-thiosulphate: thick black mud of lead sulphide formed.

Amalgams of lead and 10 per cent. and 5 per cent. of mercury: coating had no stiction.

Alloy of lead and zinc: this was not so easily attacked as one might expect.

Lead hair in solution sodium hydrate and sulphide: the solution got yellow, and deposited sulphur on the oxidised plate.

Lead in solution of ammonium chloride: was no better than the similar cell with sodium chloride. No doubt a little nitric acid was formed, but the cell was not a success.

Cells were tried with solutions of potassium fluoride: The plates were not formed well.

Lead in potassium sulphides: not much attacked; the action of the sulphide seemed uncertain, and is partly dependent on the amount of hydrate present.

Lead plates in solution of salt, with felt between: after reversal this gave good spongy lead, but a great deal of the peroxide was loose and detached.

Lead with various mixtures of sulphides and carbonates and nitrates: none of these gave deposits which would reduce well—they were all too loose.

Lead in sulphuric acid: just diluted enough to make it conduct; the anode was not much attacked.

Lead in a mixture of sulphuric and nitric acids: more quickly formed.

Lead in nitric acid alone: eaten through very quickly. The action of nitric acid on a lead plate is very peculiar. Most of the solutions already mentioned attacked the plate evenly and oxidised it gradually through, but nitric acid makes pits and round holes. As nitric acid seemed by far the best means of quick formation, several experiments were made with it. Plates were eaten wholly through with acid which was too strong to dissolve much nitrate; the acid was then siphoned off and replaced by a solution of sodium sulphate and reversed. There was difficulty in reducing the lead sulphate; it formed cakes which did not make good contact with the plate. The great objection to the various methods of forming above described is that the coatings produced have too little stiction to reduce well. When lead was the anode in nitric acid no peroxide was produced. Of course no peroxide is formed when the plate is in contact with sulphuric and hydrochloric acids, as peroxide of lead liberates chlorine in an acid solution, while chlorine precipitates lead peroxide from an alkaline solution of the lead salt.

The best solution we tried for forming plates was a mixture of dilute sulphuric and acetic acids; this solution made a fine and adherent coating which reduced well. One of the most obvious disadvantages of such solutions as dilute nitric acid is the difficulty of getting rid of the least traces of acid; of course, traces of such things as nitric or hydrochloric acid in a cell may be very destructive, or they may be quite harmless. Acetic acid can easily be driven off as vapour, and nitric acid might perhaps be reduced to ammonia and then volatilised.

Mr. Brush heats his plates to accelerate their formation; we did not try this.

Local Action.—To reduce the local action in the peroxide element we tried amalgamating the plates; this did not act. We tried to gild lead plates, but did not succeed; a gold sleeve link seemed to act well as a support for a little peroxide plate, and it was hoped that gilding might preserve lead. We tried to protect lead by various sulphides. These experiments seem absurd; in fact, many of our experiments were rather wild; but the supposed method of protecting plates has recently been patented by no less able a chemist than the late Mr. Tribe. Lead was fused with various proportions of galena, and the resulting substances were tried as anodes. Galena itself is at once coated with lead sulphate when used as anode in dilute sulphuric acid.

Lead was also combined with arsenic by heating in glass tubes. This was very troublesome work, as the arsenic was apt to volatilise, and sometimes the tubes broke, and the laboratory had to be abandoned until the smell was gone.

Double sulphides of antimony and sulphur bases were tried, but were of no use. In our provisional protection, applied for in 1883, we mention coating the plates with lead sulphide by means of thiocarbamide. This idea was taken from a receipt seen in a copy of the *Plumbers' Times and Paperhangers' Gazette*, or some such paper, which was sent me with an intimation that I had no business not to take in my trade journal. Thiocarbamide could not be bought, and was too troublesome to make, so this plan was not tried. The process is said to produce a beautiful polished adherent coating of lead sulphide on lead, or even on organic substances such as netting, and is of very considerable interest, and perhaps of commercial value.

Silver was tried as peroxide plate in various solutions. It behaved very much like lead, though it is not so easily attacked by sulphuric acid; peroxide of lead sticks to it well, but of course it is too expensive for commercial use. Silver might be used for connections. Most metals exposed to the action of the spray from secondary batteries are attacked, and make bad contact, but silver may be laid across the top of a cell without tarnishing. Probably electro-plated copper would do as well. Very few experiments were tried with platinum because of the expense. Mr. Brush has patented plates made of an alloy of lead and platinum. Most likely it would take a very large proportion of platinum to protect a plate, as the alloys of platinum are easily oxidisable. No doubt Mr. Brush's invention is only waiting for the discovery of a platinum mine.

Local action may be a very serious evil in reduced plates, especially with strong acid. Local action on the reduced plate must not be confused with local action on the peroxide plate. It does not here take place whenever a clean surface of lead is exposed to the acid, but when a body sufficiently electro-negative to lead comes in contact with it, and enables the spongy lead to combine with the acid by evolving hydrogen from the electro-negative body. In some cases reduced plates in dilute sulphuric acid give off little bubbles of gas continuously for a couple of weeks. Spongy lead seems to have very nearly strong enough affinity for the electro-negative radicle of sulphuric acid to combine by evolving hydrogen, more especially if the acid is strong. It seems likely that traces of some metal even slightly negative to lead may start local action. Platinum and lead, for instance, decompose dilute acid at once; but perhaps traces of arsenic or antimony in the oxides from which the reduced coating has been made, or in the acid, may sometimes produce the same result. Peroxide of lead, on the other hand, is more stable, though when heated with strong sulphuric acid it seems to evolve some oxygen and turn lighter in colour.

Electro-gilded copper was attacked at once by sulphuric acid.

(*To be continued.*)

LEGAL INTELLIGENCE.

Edison and Swan United Electric Light Company v. Woodhouse and Rawson.

The Attorney-General resumed his arguments in this case on Friday morning last. He directed the attention of the Court to what constitutes the subject matter of a patent. He submitted that if their lordships held that Edison's claim could not be regarded as subject matter of a patent, they must find that it had been anticipated, and he put it boldly before them, as he had done on the previous day, that nobody could have made

Digitized by Google

the patented article from the whole of the knowledge, Swan's included, prior to the date of Edison's specification; and if that were so, they could not come to the conclusion, as a matter of law, that Edison was not fully entitled to his second claim. He said that they could not put so wide a construction upon claim 2 as to bring it within any one of the whole of the anticipations which had been referred to by the other side. Unless he had wholly misconceived the evidence, the case of his clients was not that they desired in any way to narrow the claim in order to support the validity of the patent. Their case was that, to-day, with the existing knowledge if there were put before a competent workman, who did not know of Edison's patent, the whole of the previous instructions, and he were asked to make from those instructions an incandescent electric lamp, he could not do it. The Attorney-General then read the evidence of Dr. Odling in support of this contention, and said that unless the defendants were prepared to throw it overboard, it absolutely destroyed the suggestion that a filament could be obtained from any information given to the world by Pulvermacher, Van Choate, or others, and if their lordships, having regard to the weight and authority of that evidence, given by men of great scientific attainments, said that Edison's specification was not good subject matter of a patent, they would be striking at the root of the law which had protected to their inventors the most useful and ingenious discoveries of the last fifty years. He next referred to the evidence of Dr. Franklin and Sir Frederick Bramwell on the subject of high and low resistance in the conductor, and proceeded to remark that he did not at all say that the object of Edison's patent was simply to obtain high resistance by reducing the cross-section, which could have been achieved by putting in a non-conducting material; but, assuming that people knew how to get the required resistance by cutting down the carbon, they had absolutely failed to get a good lamp. They never got further than Swan, and why did his clients succeed afterwards? Because they made the filament before it was carbonised. The merit of this patent, therefore, was not so much in its reducing the sectional area as in the way in which it was done. He then cited Heywood *v.* Hamilton from the legal decisions in the "Record of British Patents," in which Lords Justices Brett and Bramwell held that a new combination of an old machine producing a new commercial article might be made the subject matter of a patent because that combination, to all intents and purposes, made it a new machine. On that assumption he claimed that Edison's combination was not only new in itself but the carbon filament had not been known before. If the case just quoted could be regarded as a description of a particular machine, *a fortiori* Edison's was a particular description. For the first time a successful incandescent electric lamp containing a carbon filament within the description of filament in the specification and the other three parts which went to make up the combination which Edison claimed, was produced and made a commercial success. The Attorney-General next cited Neilson *v.* Bedwin, in which Lord Westbury held that the nature of the antecedent information to make a subsequent patent invalid must be such that persons of ordinary knowledge of the subject would at once perceive and understand, and be able practically to apply the discovery without the necessity of making further experiments and gaining further information before the invention could be made useful. He then proceeded to say that he did not wish to draw comparisons, but it was absolutely impossible for him with his limited knowledge of scientific discovery to imagine a case in which that doctrine was more remarkably illustrated than the case just referred to. For thirty years people had been striving to make the electric light a success. For the last sixteen years Mr. Swan, Mr. Lane-Fox, and a number of other men had all been as it were leading up to it, and yet they stopped short of the point of success. He would even go further and say that in consequence of that they were absolute failures, and so remarkable was this fact that the witnesses showed that everything, Swan's lamp included (which was undoubtedly the best up to his day), could not have produced Edison's combination. Moreover, there was no particle of evidence which went to show that there was any difference between a patent for a combination and a patent for anything else. If a combination was subject matter for a patent—as undoubtedly had been held by the House of Lords—then prior information of Mr. Edison's combination must be proved to make that patent invalid. It was no good to say, "We can find a vacuum, or a filament, or a carbon pencil used before Mr. Edison's combination." If they were to give proof of the anticipation of that combination they must find an antecedent combination which came within the description given in the specification of the second claim. This doctrine was most pointedly brought out by Lord Cairns in the case of Harrison *v.* The Anderston Foundry Company. In conclusion he submitted, that on the evidence and on the legal authorities he had quoted, that if this invention, which was absolutely a new commercial article, producing extraordinary results, were not to be protected, it would simply wipe out a very large portion of the patent law of this country.

On Saturday morning, in the absence of the Attorney-General, Mr. ASTON, Q.C., resumed the arguments on behalf of the Company, principally directing the attention of the Court to the law of patents bearing upon the case, and quoting a number of judgments, notably those of Otto *v.* Linford and Hill *v.* Evans, in support of the second claim.

Sir HORACE DAVEY, in replying, said that the Attorney-General, and to a certain extent Mr. Aston also, had attached, in his opinion, far too great importance to the fact—which he (Sir Horace) would take to be a fact—that it was proved at the trial that a workman could make a lamp (and a good one, he would admit) from the description in the specification; and the argument used by the Attorney-General was this, "That inasmuch as the sufficiency of the specification has been either proved or admitted (it did not matter which for the purpose of argument), *ergo*, you cannot quarrel with the wideness of the claim." That seemed to him (Sir Horace) to involve a fallacy of language. "Sufficiency of specification" might mean two totally different things. It might mean either that there was a sufficient description in the specification to enable a workman to make a lamp which would be within the claim, or it might mean that there was sufficient description in the body of the specification of that which was claimed of the patentee's invention. He was not prepared to dispute, nor did he desire to dispute, that it was proved at the trial that a workman could, by taking the specification in his hands, make a lamp from the description which would be a lamp within the claiming clause. At the same time, it had been disputed, and Mr. Jamieson gave some evidence about it. But it was never a serious matter of contest whether there was a sufficient description to enable a workman to carbonise ordinary fibrous vegetable matter. A workman could take a strip of bamboo fibre which would be a fibrous vegetable substance within the meaning of the specification, and the description or terms in the specification would be ample to enable him to carbonise that vegetable material, and, having done so, to place it in a lamp for the purpose of a burner. But that was a totally different proposition from what was claimed. What his clients alleged, and, in fact, he did not think he was exaggerating when he said it formed nine-tenths of his argument in the Court below, and which, according to his conception of the case, formed the strongest part of it before their lordships, was this, that assuming the second claim to bear a wider construction than that which had been put upon it by the learned judge, what they denied was that there was any sufficient description of what a filament was to be found within the four corners of the specification. Or in other words, they denied that the patentee had particularly described and ascertained the nature of his instrument as claimed in his claiming clause. The words in the Act were, that the patentee was "to particularly describe and ascertain the nature of his invention." It was in that sense that he submitted to their lordships and made it the foundation of his argument, that the specification was insufficient. Or the argument might be put in another form, that by his claiming clauses the patentee in this case had claimed something which he had not described in his specification if they bore the construction which the Attorney-General put upon them. He (Sir Horace) might be right or wrong as to that, but whether right or wrong, it was not enough to say that a workman by taking a specification in his hand could carbonise a strip of bamboo and put it into a lamp. The specification might describe in the most careful and minute manner a process by which a workman could produce the patented article, but if the claiming clause claimed as the patentee's invention something which was not found within the four corners of the specification then it was not particularly described. It appeared to him (Sir Horace) that the difficulty which his learned friends, with all their experience and ability, and all the thought which they had of course given to the subject, had in putting an intelligible meaning upon those words of the second claim (which was the real subject of dispute) was indicated by the difference of view put forward in their arguments. Mr. Aston's final definition of a carbon filament was this:—"A carbon filament within the second clause means a carbon conductor of small cross-section, of great length, possessing such an amount of flexibility and resilience as will allow of expansion under the influence of heat." The first observation that he (Sir Horace) would make upon this was that it was not necessary that high resistance should enter into a carbon filament, which applied to both his learned friends' arguments and to the claim itself when they came to look at it, because while the first claim spoke of a carbon filament of high resistance the second claim spoke only of a carbon filament, being therefore not confined to high resistance, so that high resistance did not enter into Mr. Aston's definition at all, inasmuch as the resistance depended upon the length as well as the thickness, and such a conductor might be of comparatively low resistance. With regard to flexibility he had already said, and he would now repeat, that it was impossible for his learned friends to find from the beginning to the end of the specification any passage in which flexibility was spoken of as one of the characteristics of a carbon inductor or filament when it was prepared for use in a lamp. It was undoubtedly true that the patentee did speak of flexibility with reference to the filaments, but their lordships would observe that the flexibility was spoken of (and this he would show from the evidence of the scientific witnesses) with reference to a filament, strip, or wire, before it was carbonised, and not after it was carbonised. Indeed, he would go so far as to say that the mind was carried away from the idea of flexibility being an attribute or desirable characteristic of the carbon conductor when formed for the purpose of being put into a lamp, by their being actually told that provision was made for its stiffness and not for its flexibility. [Read specification.] So far from that being a fancy of his own, both Dr. Hopkinson and Mr. Imray pointed out that stiffness and not flexibility was a thing to be aimed at. Mr. Imray said that there was to be sufficient flexibility before, and stiffness after carbonisation. His learned friends had been guilty of some fallacy in speaking of flexibility. What did they mean? There might be flexibility in the sense in which a thread was flexible upon which they could tie a knot. Or they might have flexibility in a cane which might be bent into an arch. Flexibility in that sense was merely a question of degree. The flexibility which was wanted before the carbonisation and the filament had received its shape for the purpose of winding it round a bobbin or winding it into a spiral and maintaining it in that form was a totally different thing from the flexibility to which his learned friends alluded so much in the Court below. They said now something of this kind, "That the flexibility of these burners is a flexibility of quite a different character, and wherever you find flexibility spoken of in the specification it is of the first kind you alluded to, and not of the second kind."

Lord Justice FRY: Putty, I think, was the illustration.

Sir HORACE DAVEY said that was so. He did not say it was any answer to a patentee to say "You did not see all the advantages of your invention." He was not suggesting that. But he did say this, that where an

Digitized by Google

expression was used, such as "carbon filament," without any express definition of it, and where the patentee, or those who represented him, gave a definition at the Bar of that, then they must find that definition within the four corners of the specification, or they must find if he had not given them that, a definition with reference to those particular advantages. He made the same remark with regard to "resilience," which was not spoken of there at all. So that he concluded that these two conditions that Mr. Aston laid down, of "possessing such an amount of flexibility and resilience as will admit of expansion under the influence of heat" did not form any part of the definition of a carbon filament as used by Mr. Edison in this patent, so far as that gentleman's meaning could be gathered from the specification. As to cross-section, he asked what amount of cross-section, what length would make the thing a filament? He would merely remind their lordships that the witnesses one and all said that this was merely a matter of degree. They could not draw the line. They had no guide given by Mr. Edison himself, except that it was to be, if one might judge from the words of the specification, of "such smallness of cross-section and comparative length as will give a high resistance of from one to 500 ohms," and the wire which he spoke of was so small as seven-thousandths of an inch. If the carbon filament was to be of "small cross-section and comparative length as will produce high resistance," then he would show their lordships presently that a carbon filament of that definition had been previously described and published. Having referred to Otto *v.* Linford and other cases, he said: If Mr. Edison had confined himself to claiming what his clients contended he did claim, the making of a lamp which contained as one of its constituent elements and as part of the combination, a carbon filament made in a mode pointed out and described with considerable detail in the specification and shown in the figures, then there could have been no objection taken to it. Whether it might or might not be anticipated by an earlier patent he was not now upon, but so far as the claim itself was concerned Mr. Edison would have been in the enjoyment of his patent. But having put in one thing he put in a claim which not only covered what was described, but a great deal more; yet by his greediness—if he might use the expression not in an offensive sense—Mr. Edison had done, what patentees often did by grasping at too much, destroyed the validity of his patent, and that was the point which he (Sir Horace) desired to bring to their lordships' attention on this question, that being the mere matter of degree, and the patentee not having told either in figures, bounds, or any other mode, what it was that he intended to claim, the second claim could not be held to be valid.

On resuming on Monday, Sir HORACE DAVEY proceeded to endeavour to show that the failure of Swan's lamps was due to overcharge of current or bad manipulation rather than to any inherent defect in the lamp itself. Whatever importance was to be attached to the question whether Swan's was or was not a successful lamp, the evidence, when properly understood, did not go to support the contention of his learned friends. And assuming that Edison's patent did not bear the large construction which the Attorney-General claimed for it, but bore a smaller construction, was there or was there not evidence of infringement? He would endeavour to clear the ground upon this subject as far as he could. His learned friends, as far as he understood their arguments, did not raise the question which they did in the Court below, and impressed upon the learned judge that there was evidence that Woodhouse and Rawson's lamp was an infringement of the first claim, or, in other words, they did not now ask their lordships to differ from the learned judge who held that there was no evidence to show that Woodhouse and Rawson's lamp was made as described. It was said, and this was the point which he had to put, that Woodhouse and Rawson's lamps were infringements of Edison's patent—first, because they contained a burner which was of small cross section compared with its length, and had a certain amount of elasticity and resilience. He had already said, and he would repeat, that if that were the true construction of Edison's patent then he must plead guilty, because undoubtedly the burners of Woodhouse and Rawson had a small cross-section in comparison with their length, and they had a certain varying amount of flexibility and resilience. But he had already addressed their lordships for the purpose of showing why that could not be the construction of Edison's patent, and why, if it were the construction of it, the patent was too large or too vague, and did not sufficiently ascertain and describe the nature of the invention. Then it was said they were an infringement of Edison's patent because there was evidence, they said, that the carbon filament or burner in Woodhouse and Rawson's lamp assumed its filament character before it was carbonised. He could only say he was not aware of the evidence upon which they relied for the purpose of showing that, except that Sir Frederick Bramwell said he did not know any other mode by which it could be made. Even Sir Frederick Bramwell said that he was not aware of what was stated to be a secret process. He attached the greatest importance, and he knew their lordships attached the greatest weight, to whatever fell from Sir Frederick Bramwell, but, on the other hand, he was not detracting from the respect they all felt for that gentleman when he ventured to say that he had yet to learn that Sir Frederick Bramwell had the faculty of omniscience. Mr. Aston, in the course of his arguments, seemed to indicate the very mode in which filaments had been or might be made. To put it hypothetically, and only for the purpose of illustration, Mr. Aston seemed to say, "You may get carbons from the decomposition of a hydro-carbon or certain oils on a glass in the form of a sheet, or like gold leaf cut in "strips." His learned friend knew very likely what he was talking about, and he (Sir Horace) called him as a witness in favour of Woodhouse and Rawson to this extent, that because Sir Frederick Bramwell said there was no mode of which he was aware, that was no evidence that no such mode existed.

Lord Justice COTTON: You have suggested that it should not have been assumed that this was made into a filament before it was carbonised. How about the last sentence of Mr. Rawson's evidence?

Sir HORACE DAVEY said he was coming to that. He was not aware of what his learned friends assumed, having no control over the operation of their minds; but he was perfectly certain of this, that if that assumption had been made it was not warranted by anything which fell from either himself, by admission or otherwise, or, according to the best of his knowledge, from his friends Mr. Charles or Mr. Macrory. It was said that Mr. Justice Butt came to the conclusion that it received its filamentary character before it was carbonised. He had read through the learned judge's judgment again, and he could not find anything of the kind. He could not contend that he had read through all the casual observations at the trial, but he did not think that any interlocutory remark could be found to have that effect. The only thing left them was Mr. Rawson's evidence, and he ventured to say that that was an entire misunderstanding as to its meaning. He would go further than that, and say that if his learned friends intended to rely upon this point as against Mr. Rawson, the least they could have done was to have asked Mr. Rawson straight out. They might say they did not desire to pry into Mr. Rawson's secrets. He would give them full credit for their desire to respect the sanctity of Mr. Rawson's manufacture. At the same time it would not have been unduly interfering with Mr. Rawson's secrets, if they intended to rely upon this, to say that was a crucial test of whether there was an infringement or not. They asked Mr. Rawson a great many questions, and they ought to have asked him this question:—Do your carbon conductors assume their filamentary character before they are converted into carbon? The Attorney-General had referred to the final question in Mr. Rawson's evidence, in which there was an ambiguous reference to carbonising, which he (Sir Horace) understood—though he admitted it was ambiguous—and which the learned judge understood, and which was, he thought, understood by everybody in the court. His learned friends were not entitled to draw an inference from an ambiguous reply on a vital question, when it was open to put a direct question which they did not venture to do. [He read the evidence to show that what they were dealing with there was "flashing"—that is to say, that there was a further deposition of carbon after the conductor had assumed its filamentary character, after it had been manufactured, and after the lamp had been made, similar to that described by Sidot and Lane-Fox.] He was entitled to say, in conclusion, that if his learned friends had nothing better to rely upon than this ambiguous expression, in order to fasten a charge of infringement upon Mr. Rawson, then it was their duty to clear up the matter by bringing out what was exactly in Mr. Rawson's mind. They had no affirmative evidence to support them, and they declined the offer that a report should be made by an independent person upon this point. Moreover, Mr. Rawson said that he was willing to make the offer again; and, if their lordships thought that a report should be made, he (Sir Horace) would now repeat the offer on behalf of his clients.

Judgment was reserved.

COMPANIES' MEETINGS.

The Gulcher Electric Light and Power Company (Limited).

The fifth ordinary general meeting of the shareholders of this Company was held at Cannon-street Hotel, on the 20th inst., under the presidency of Mr. Daniel de Castro.

The SECRETARY read the minutes of the last meeting, and afterwards read the notice convening the present meeting.

The CHAIRMAN stated that the notice just read was ordinarily printed on the back of the annual report, but he was sorry they had not been able to do so this time. They were interrupted in the middle of the audit by an order to take their books to the Court of Appeal on the hearing of Mr. Gilman's appeal against Mr. Justice Grantham's judgment in favour of the Company, an appeal which was dismissed with costs. The audit, however, through the books being at the Court, had been postponed for a week, and consequently many of the shareholders might only have received the report and accounts that morning instead of a week ago, as had been customary.

A SHAREHOLDER said it would have been better to delay calling the meeting.

The CHAIRMAN said he quite felt the force of any shareholder objecting that he had not had time to consider the report, and he would be quite willing to adjourn the meeting if the shareholders desired that course should be adopted.

Mr. A. J. KING said he thought that if the Chairman proceeded with his address the shareholders would obtain all the information they required.

The CHAIRMAN, in the course of his remarks, said: As no adjournment is moved I think, having regard to the shortness of time you have had to consider the report, that it would be well if I read a part of it. It says:—It will be observed that the accounts of the past year are presented in a somewhat unusual form. Those for the nine months ending June 30th, 1886, are believed to be absolutely accurate. They are absolutely correct, and have been signed by the auditors. Those for the 12 months ending September 30th can only be approximately correct. The reason for this apparent irregularity is that the Directors resolved to alter the period for holding the annual general meeting, and to make the Company's financial year end in future on June 30th. The advantage to be gained by this change is that the annual stocktaking (which is a very laborious and lengthy process, involving among other hindrances to business the closing of the works for at least a week) will in future take place in July, when

Digitized by Google

the electric lighting business is slackest, instead of in October, which is one of the busiest, if not the busiest month in the year. In accordance with this decision, stock was taken last July. The accounts up to June are absolutely correct, but between June and September they are only approximate accounts, for we have not the accounts based upon the second stock taking. Mr. Mountain, our manager, has very carefully examined into the outgoings and incomings, and has estimated his stock as nearly as possible. Those shareholders who had preserved the reports and balance-sheets yearly would be able to satisfy themselves as to the progress of the Company, and on page 3 of the report your attention is drawn to a few facts which I think deserve your consideration. I have there begun by comparing the position of the Company as far as its liabilities are concerned. On the 30th June, 1883, when we took over the Company, the share capital of the Company consisted of 47,747 shares, of which no less than 19,660 had been issued to vendors as fully paid up. On the 30th June, 1886, the total share capital of the Company consisted of 20,097 shares (since reduced to 19,633 shares), of which 5,964 only are vendors' paid up shares. Of these 5,964 shares Messrs. Fox, Johnson and Garrett, the vendors to the Company, are under covenant to surrender 1,374, and if we are successful in the action pending to compel the surrender of these shares, there will be rather less than 4,600 vendors' shares with which the Company will be burdened. On the 30th June, 1883, the other liabilities of the Company were admitted by the Board to be £19,313. On the 30th June, 1886, they were only £7,265. The liabilities have therefore been enormously reduced in each direction, On the other side of the balance-sheet the plant and stock on June 30th, 1883, was alleged to be of the value of £20,000. You will remember very well the discussion that took place at the first general meeting, at which it was admitted that that was the only the roughest estimate, and afterwards that £20,000 was found to be so far in excess of the value of the stock that in a subsequent year we wrote off £2,000. The value was really nothing like £20,000, it was nearer £12,000. The trade accounts due to the Company at the 30th June, 1883, were £1,106, and the cash at the bank was £2,560 (the Directors having just then made a call). On the 30th of June, 1886, plant and stock stood at £31,251, which has been most carefully valued; the trade accounts due to the Company at £1,900, and the cash at the bank at £97. Every one of the assets has considerably increased. Referring to the manufacturing and trading accounts for the 14 months ended 30th June, 1883, the total works expenditure was £24,000, of which £2,876 was charged for superintendence. The result of this expenditure of £24,000 was sales amounting to £5,600, and the admitted manufacturing loss on the 14 months in question was £6,874. For the nine months ended 30th June, 1886, the total works expenditure was £13,000 (very little more than half the works expenditure before; and on the opposite side of the account, in the nine months, we have sold £11,500, just double what was sold before, and there was a net manufacturing profit of £828, against an admitted loss of nearly £7,000 for 1883. In this department also, in which the sales, &c., have been raised from an average of £400 per month to an average of nearly of £1,300 per month, and where a manufacturing loss of nearly £500 per month has been converted into a manufacturing profit of nearly £100 per month, the Directors desire to add that the improvements have also been most steady and continuous. This is not an accidentally favourable balance-sheet that we are comparing with the original balance, but one that has grown from a terribly bad position into the present hopeful one. Coming to the profit and loss account for the fourteen months ended June, 1883, the total head office expenses were £4,724, including £1,750 which was paid for Directors' fees, and £782 for law charges, the deficit for that period being £18,578. For the nine months ended June 30th, 1886, the total head office expenditure was £2,130, while the deficit for the nine months has been reduced to £1,268. The above figures also speak sufficiently for themselves, but as there is even yet a balance to be carried to debit on this account the Directors desire to compare it with the same account as presented in 1885; and whereas in 1885 the head office expenses amounted to rather more than £360 per month, the same expenses for the nine months ending June 30th, 1886, were somewhat less than £240. On the other hand, whereas in 1885 only £121. 14s. 6d., or about £10 per month, was carried to the credit of this account, £862. 17s. 11d., or upwards of £90 per month, has been carried to its credit for the nine months ended June, 1886. So that, while the head office expenses have been reduced during the last nine months by one-third, the trading profit has increased ninefold. This is a comparison with even last year's accounts. Last year I told you that I saw no reason why our head office expenses should not be reduced ultimately to £2,500 a year; and I am glad to say that this year, notwithstanding very heavy law charges, they have been reduced to £2,600. These economies are being extended in every direction at the works, while the trading increase is being maintained. Not only has it been maintained during the three months from June to September last, but I may tell you that it has been much more than maintained since September—it has been very largely increased. I referred to a deficit of £1,268 on the profit and loss account for the nine months to June last, but more than half of that is due to law charges, which, however, heavy as they were, were only half of what they were last year. We have reason to believe now that there is an end of the litigation which commenced three years ago with our promoters—the original Directors. On the whole, we have succeeded very well in recovering from the old Directors by a compromise and arrangement a very large proportion of that which they claimed. Mr. Blundell, on the other hand, insisted on his strict legal rights, and these he obtained in a court of law. Our case was never heard, for our junior counsel was not there, and our leading counsel required his assistance. But for that I am very confident that even Mr. Blundell, our late chairman, would not have maintained his claim. I am sure you would not wish the litigation prolonged by referring the matter to the Court of Appeal. There is an account dealing with the Gülcher patents, the Crookes patents, Mr. Blundell's disputed fee, and certain bad debts. Those items are all placed below the line in the profit and loss account, because they are debits which are not attributable to the business of the last nine months. With reference to the Gülcher dynamo, I hope the shareholders will approve of the course which the Directors have taken. What we have tried to do is to avoid shams, whatever else we do. The price paid for our patents was infinitely more than they were worth if they were ever patents at all, and last year it became necessary for us to consider whether we would continue the Gülcher dynamo patent in existence. We came to the conclusion that we would not, that if it were an English patent at all it was for a machine that was now quite obsolete. We therefore decided not to maintain the patent, and we have therefore let it lapse and have written off what we consider the price at which it has been estimated. There stood in our balance-sheet the sum of about £22,000 still due for the Gülcher patents. They were all bought in one sum for £100,000, and there was no division, no allocation of so much to lamps, so much to dynamos, &c., but we had to settle what we would write off for the dynamo, and the fair and business way was to ascertain what might be the fair value of the lamp patents. The lamp patents are good for an excellent lamp which has held its own in the market. We have written them down as worth £2,000, treating the dynamo patents and all that was paid for them as the balance. That involved our writing off £20,000. As a matter of fact, we are no richer or poorer for that. It is a mere matter of account, and it will perhaps enable us to know more where we are. If we had maintained the patent, we, in common sense, ought to have insisted upon enforcing it, and we should have had to bring actions against two or three of the most important companies for infringing what was possibly once a patent, but if so, it was so very slight, that I do not believe we should have succeeded in getting any damages at all. The next item written down below the line is in reference to the Crookes lamp. As a matter of fact we are continuing even now to have a few of the Crookes lamps returned on our hands, with plaintive appeals to allow something for them. However, as to the £400 which we refer to in the report, we felt that we were bound to credit our New Zealand agents with that amount. They have in their hands £7,000 worth of these lamps, which had been sold to them at very high prices, but which they had never been able to do anything with. We are using up those lamps in our shops, and we find the complaints made about them by our agents is true. Directly one is put up it may go out, while another which is put up may last a week. We do not know how long they may last. Mr. Blundell's disputed fee account I need not refer to further. We settled with all the former Directors on very advantageous terms. The item of £638 which is also below the line represents several debts due from various companies and customers, some of which have been standing as assets almost from the commencement of the Company, and all of which are bills of doubtful value. Having given the detailed particulars as to the items comprising the total amounts, he continued: What I wish you to see is that this £638 does not mean any large number of bad debts which have been incurred by us. Having referred to various other items in connection with the annual manufacturing accounts for the year 1883 to further emphasise what he had already pointed out to show the gradual improvement in the position of the Company, he proceeded: The shareholders will thus see that there have been a gradual and steady decrease in the liabilities, and a steady and gradual increase in those items which indicate profit. Since we last met we have issued £5,000 of debentures, which you gave us power to issue. You will remember that last year we had no power to issue debentures because our capital was called up. We obtained the permission of the shareholders, and we applied to you then for the money. We found our wealthy shareholders would not part with their money, and we had the greatest difficulty in getting this £5,000 from the shareholders. Up to the present we have had the portion of this money which has been subscribed by the shareholders from those who have stuck to us from the first. From those gentlemen we have succeeded in getting £3,000, and the other £2,000 has been subscribed by your Board. I do not take any credit for having subscribed that amount in conjunction with the other Directors, although I am your largest debenture holder. I mention it as a matter of encouragement, because I think it shows that those who know best about the position of the Company have the most confidence in investing their money in it, and for that reason we have not hesitated as a Board to take up this £2,000. We are now going to do business. We are not going to drag along as we have been doing. Though there is a deficit, still we have done with deficits, and we are going to do business, and to do business we must have more money at our command. We do not want at present very much, but we have taken power as a Board to issue £20,000 of 7 per cent. debentures, and we have explained to you in the report how we propose to deal with that. We propose to keep £15,000 for the purpose of issuing it as we require to do so. If we get a very heavy order (and we have two or three in view), which our working capital is altogether inadequate to carry out, we should invite you to subscribe so much towards that particular order. These debentures will only be a second mortgage at present, because the £5,000 of mortgage debentures which we have already issued must remain a first mortgage. Of this second issue, however, £5,000 will be reserved for paying off the £5,000 of the first issue when it becomes due, so that before the year and a half now remaining for the first mortgage debentures to run off this proposed issue of £20,000, will spring into a first charge. He then referred with regret to the retirement of the late secretary (Mr. Russell Day), and spoke in approving terms of the services which that gentleman had rendered to the Company. Continuing, he said: You know the business of this Company has been practically carried on by what is called a "Works Committee," which consists of Mr. Mountain, our manager, Mr. Fricker, our electrician, and myself, who act as a sort of mediator or looker-on. We owe a great deal to both those gentlemen for the position in which

Digitized by Google

you are. You would not be where you are had it not been for Mr. Mountain and his exertions, which have been almost superhuman. It is to him mainly that you owe the fact that the Company has been got into the position in which it now stands. I hope some one will second the vote, which I intend to propose, of 50 guineas to that gentleman, as an honorarium. We have elected two new Directors, who will really, I hope, assist us very materially. We have not been a very powerful Board—certainly not very much known in the world, and we have not represented any very large and powerful people. Mr. Grëwing, of the firm of S. Oppenheim and Company, has consented to come on to the Board and assist us in every way he can, and the assistance of such a firm will be very material. Mr. Thomas Lloyd, who has also a very considerable interest in the electrical world, has come to a like conclusion with Mr. Grëwing, and has also joined us. Each of these gentlemen started by taking £250 debentures merely as a kind of earnest that they mean business. Mr. Grëwing is chairman of the Austrian Company, besides being a Director of one or two telephones companies, and Mr. Lloyd is a director of the River Plate Telephone Company. In the ordinary course I believe it is customary for them to resign together with the other retiring Directors, who are Major Cotton and Mr. Wallace. The Auditors, Messrs. Wm. Edwards, Jackson and Co. (to the value of whose services he testified) also retire, and offer themselves for re-election.

Mr. Murray asked what the Directors proposed to do with the deficit of £71,000 in the balance-sheet.

The Chairman: That loss of £71,000 is a loss which we shall never get over. We have discussed this question at our former meetings more than once, and when we get the shares from Messrs. Fox, Johnson, and Garrett, for which we are suing them, we propose to bring a scheme before you of reducing our capital down to the present value of the shares. That is to say there is now something like £32,000 or £33,000 which we consider absolute assets in stock plant, patents, money, and consignments. If you take away from that the trade debts, there remains a surplus of £25,000 or £26,000, and we propose to reduce our £100,000 capital by three-fourths, down to £25,000, and then we shall be in a position to declare a dividend out of any profit we earn. At present, if we earn a profit next September (and I hope we shall), that must be carried to the reduction of this loss, and unless we make the reduction of the amount mentioned, no possibility of dividends can be looked for in our life time. If, however, we carry out that proposition, I see no reason why this Company should not be a dividend-paying concern in the course of the next two or three years. There is a further idea that I have ventilated, I think, in this Company. My idea is that we might then increase our capital to £50,000 by making those shares which have been issued one-half paid up, but that could only be done with the consent of the shareholders. By that means we should be able to raise our debentures at 5 per cent. instead of 7 per cent., because there would be the security of the unpaid capital as well as the security which constitutes the security of the debentures at present. Of course there is the extra liability, and some shareholders might shy at that, but I think if we carried out that proposal we should get a quotation on the Stock Exchange, and in that case those shareholders who shy at the liability might easily get rid of their shares on the Stock Exchange at their full value. This matter will be brought before you again before the end of the current Gülcher year, and those who have heard what I have said on the subject now may think between now and then of some modification that may be an improvement on my idea.

Mr. King thought that the Chairman's statement, showing the progress of the Company, could not be other than satisfactory to the shareholders. It was, of course, very unsatisfactory to find that the capital required to be written down to the extent of 75 per cent.; but they must all recognise that this heavy writing off was not in the least degree to be referred to the want of skill or attention on the part of the present Directors, but to the hallucination which existed three years ago with regard to electric lighting, when fabulous sums were given for all sorts of patents which in the end proved to be worthless. The Chairman, with his characteristic straightforwardness had told the shareholders the worst, and he (Mr. King) thought they were all now resigned to the fact that the proposal mentioned by the Chairman for reducing the capital was necessary. He had no doubt, however, that the shareholders would take upon themselves the liability to which the Chairman had further alluded for the sake of improving the position of the Company. Those who might not be inclined to face the liability would at all events have a market to see what their shares were worth. He thought that the Board and the shareholders were to be much congratulated on the accession of able and influential men to the Board.

The Chairman then moved the adoption of the report and accounts.

Mr. Lloyd seconded the motion, which was carried unanimously.

A hearty vote of thanks having been accorded to Mr. Russell Day,

The Chairman proposed a resolution awarding 50 guineas to Mr. Mountain for his labours as managing director.

A Shareholder seconded the motion, which was carried unanimously.

Mr. W. C. Mountain in reply expressed his belief that if they continued to pull together they would ultimetely make the success of the Company.

Resolutions were then passed re-electing the Directors and Auditors.

Mr. King afterwards proposed a vote of thanks to the Directors for their successful conduct of the Company's affairs. They had a most admirable Chairman, and if man's energy could rescue a moribund company, Mr. de Castro had given evidence of his capacity and energy. He fully expected to see the day when the Company would be paying satisfactory dividends.

Mr. Woodly seconded the motion, which was agreed to *nem. con.*

The Chairman acknowledged the compliment, and the proceedings terminated.

The New Telephone Company.

The annual meeting of this Company was held on Saturday last. We shall give the detailed report in our next issue.

NEW COMPANY.

The Taunton Electric Lighting Company (Limited) was registered on the 16th inst. by H. F. Kite, 11, Queen Victoria-street, E.C., with a capital of £10,000, divided into 2,000 shares of £5 each. The object of the Company is to carry on as a going concern a business hitherto conducted by Henry George Massingham, at Taunton. The Company is registered without Articles of Association, and the regulations of Table A in the Act of 1862 apply.

NOTES.

AMSTERDAM.—Messrs. Siemens and Halske, of Berlin, are about to establish a central lighting station in Amsterdam.

REPAIR OF AN ATLANTIC CABLE.—One of the Atlantic cables which has been broken for six weeks past off Land's End has just been repaired.

RIO DE JANEIRO.—Arrangements have been concluded by the Tramway Company of this city to give the Julien system of electric traction a trial.

REMOVAL.—Messrs. H. and E. J. Dale inform us that they have removed their warehouse for electrical fittings from 4, Little Britain. Their show rooms and offices are now at 26, Ludgate-hill, and their factory at 9, Kirby-street, E.C.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending December 24th, 1886, were £3,420, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

LONG DISTANCE TELEPHONY IN FRANCE.—The town of Lille is now in telephonic communication with the five following places:—Roubaix, Tourcoing, Armentieres, Dunkerque, and Bergues. It is proposed to erect a telephone line between Paris and Havre.

ACCUMULATORS.—The Electrical Power Storage Company inform us that during the last 50 days they have received and executed orders for accumulators sufficient to supply 5,150 sixteen candle-power lamps, and having a capacity equal to 3,390,000 watt-hours, or 4,543 horse-power hours.

TENDERS ASKED FOR TELEGRAPH MATERIAL.—The Bombay, Baroda, and Central India Railway Company ask for tenders for the supply of telegraph materials. Forms of tenders can be obtained on application and payment of 5s. to Mr. T. W. Wood, 54, Finsbury-circus, E.C., and must be returned by noon on January 10th.

SECONDARY BATTERIES IN THE UNITED STATES.—The Electrical Accumulator Company, of New York, has erected a large factory at Newark, N.J. This company manufactures cells on the patents owned by the Electrical Power Storage Company in this country, and is said to be backed up by powerful financial support.

PHILADELPHIA.—The city of Philadelphia does not as yet possess a central station for the domestic supply of incandescent light, although it is reported that such an undertaking will shortly be commenced. Only some three or four isolated incandescent plants at present exist in this city, while the number of arc lights exceeds 2,000.

NICKEL-PLATÉD COOKING VESSELS.—An order has been issued in Lower Austria forbidding manufacturers and tradesmen to sell nickel-plated cooking vessels. It is stated that vinegar and other acid substances dissolve nickel; and that this, in portions of one-seventh of a grain, causes vomiting, and is even more poisonous than copper.

THE AMERICAN ELECTRIC LIGHT COMPANY.—This company, which is one of the largest manufacturers of arc lighting apparatus in the States, is endeavouring to obtain a footing in Europe, and has recently concluded an arrangement whereby the firm of Wockaty and Company, of Gothenburg, become its representatives for Norway and Sweden.

PROPOSED UNDERGROUND TRAM LINE.—A scheme is to be brought forward during the next Session of Parliament for the construction of a railway or underground tramway, commencing by a junction with the already authorised City of London and Southwark Subway at Newington Butts, passing under Kennington Park-road and Clapham-road, and terminating near the junction of Stockwell-road with Clapham-road.

NEW TECHNICAL COLLEGE.—At a meeting held at Dundee on Monday afternoon it was agreed to erect a Technical Institute near University College, to be worked in connection with the college. The new building is to be known as the Baxter Technical Institute, the late Sir David Baxter, Bart., of Kilmaron, having left £20,000 for its erection, with a view to the improvement of working men in scientific knowledge.

TEMPORARY LIGHTING.—At the annual Christmas dramatic entertainment, given by the scholars of the Middle Class Schools, Cowper-street, E.C., on the evenings of 20th, 21st, and 22nd inst., the stage was lighted by Woodhouse and Rawson incandescent lamps, the current being derived from E.P.S. accumulators, which were charged in the daytime from the Finsbury Technical College, the two buildings being adjacent.

ROYAL INSTITUTION.—On Friday, January 21st, Sir William Thomson will lecture on "The Probable Origin, the Total Amount, and the Possible Duration of the Sun's Heat." The Christmas lectures commenced on Tuesday, December 28th, and are by Prof. Dewar on "The Chemistry of Light and Photography." On Thursday, January 20, and the following Thursdays, January 27, February 3, 10, and 17, Prof. A. W. Rücker will give five lectures on "Molecular Forces." Other courses of lectures will be given by Prof. A. Gamgee, Edmund Gosse, Prof. Max Müller, Carl Armbruster, and the Right Hon. Lord Rayleigh.

THE WATER POWER OF NIAGARA.—It is stated that a project is on foot for utilising in various ways the water-power of Niagara Falls, the undertaking having been taken in hand by "The Niagara Hydraulic Tunnel and Power Company." Among the objects contemplated is that of converting the waste power into electricity. The report on this gigantic enterprise says that the problem of transmitting the power from Niagara Falls to distant points is also nearing a solution. It is now conceded by practical electricians that it would be entirely practicable to light the city of Buffalo, twenty miles away, with power furnished by the Falls.

STENO-TELEGRAPHY.—It is announced that after many years of labour M. Cassagne has at length succeeded in bringing to perfection his system of steno (or short-hand) telegraphy. We fear, however, that while the apparatus of M. Cassagne has been slowly maturing, other systems—or at least one other system—already outstrips it in rapidity of transmission, and it is difficult to see that any advantage, other than that of speed, could be claimed for such a system. The speed attained by M. Cassagne's apparatus is said to be 240 words per minute ("*une prodigieuse rapidité*"). But it is well known the English Post Office now attains nearly double this speed with the Wheatstone transmitter.

WORKSHOP ILLUMINATION.—We learn from *Industries* that Herr Cohn, of Breslau, in an address to the members of the Naturalists' Association, at Berlin, made an interesting statement concerning the lighting of workshops. He has found, as the result of a long series of observations and experiments, that no working place is to be deemed well lighted by artificial means that has not a minimum illumination of 10 mètre candles. By mètre candle he understands the degree of illumination to be found upon a small disc of paper set one mètre distant from a standard candle light. With less than this, he

Digitized by Google

says, the workman's efficiency is diminished, and, in course of time, his sight is seriously weakened.

BELGRADE IMPROVEMENTS.—It is stated officially that a despatch has been received from the British Minister at Belgrade, to the effect that the Municipal Council of that city has determined to undertake some extensive operations for the improvement of the city; amongst others the lighting of the streets is to be reorganised. Concessions for this and other projects will be granted to the lowest bidder, and are open for public competition until the 10th (22nd) March, 1887. Competitors will have to prepare their own form of contract. The population of Belgrade is about 41,000. Survey plans have recently been completed, and can, it is stated, be obtained from the Mayor of Belgrade for the sum of 20fr.

INGENIOUS APPLICATION OF ELECTRICITY.—We recently mentioned the fact that electric temperature indicators were very extensively employed in the vineyards of California, for the purpose of giving warning when the temperature falls dangerously near the freezing point. Bonfires are always kept ready stacked, and they have to be lit at any hour of the night when the alarm is given. In order to save the farmers from the necessity of performing this unpleasant duty *in propriâ personâ*, many of the vineyards in the neighbourhood of San Francisco are provided with an additional arrangement whereby the bonfires are automatically lighted on the fall of temperature. This is effected by placing a little gun cotton in the centre of each bonfire, and providing a firing circuit which is closed by a relay placed in the thermometer circuit.

CENTRAL STATION AT ANGERS.—The following conditions of subscription have been adopted by the company which is running a central lighting station at Angers:—The cost of wiring and the supply of plain brackets is undertaken by the company, who will, however, employ the existing gas fittings wherever practicable. Ornamental fixtures are supplied at the charge of the subscriber. The company also undertakes the entire maintenance of the installation, including the replacement of worn-out lamps, but lamps broken by accident are charged to the subscriber. Contracts are made for a term of five years only; the subscriber pays a fixed annual charge amounting to 12fr. per lamp per annum, and also a sum per lamp-hour, as follows:—4 centimes per lamp-hour for each 10 candle-power lamp; 7 centimes per lamp-hour for each 16 candle-power lamp. Arc lamps, or incandescent lamps of more than 16 candle-power, are charged for by special agreement.

ELECTRICAL PHENOMENON.—Under this heading the following letter appears in *Nature*, December 23rd, from Mr. Thomas Higgin:—"I beg to enclose extract from a letter just received from a young friend at Yloilo, and shall be glad if you will insert it in your next issue. Some of your readers may have further information respecting this interesting sight: 'Yloilo, Oct. 1, 1886. Last night a most extraordinary phenomenon was visible in the heavens. About nine o'clock the sky was perfectly clear, all the stars visible, but no moon, when suddenly the whole heavens were lit up as if by electric light, a very large globe of fire became visible (about the size the moon appears when full) and floated slowly northwards. I was in rather a bad position for seeing where it actually went, a house being between me and the horizon. This ball was followed by smaller ones, which were close to the big one, and gradually got smaller, till they appeared like falling stars, only they went much more slowly.'"

THE ELECTRIC LIGHTING OF MEN-OF-WAR.—The success of electric lighting on shipboard has long been placed beyond all possibility of doubt or question; indeed, on all large vessels either of the navy or the mercantile marine the electric light is now regarded as an essential part of their equipment. It would, however, be a mistake to conclude that nothing remains to be done in the way of effecting improvements in the general system, and we conceive that we are doing the greatest service both to the scientific and the naval profession by indicating any points of weakness, especially when, as probably in the matter we are now referring to, the defect may be remedied without much difficulty. If our information be correct, there are certain ships of the Navy on board which the firing of the heavy guns is usually accompanied by the extinction of the light. It is true that just at present heavy guns are not as a rule fired for fear they should burst, but it is none the less necessary that all parts and fittings should be of sufficiently solid design to withstand the heavy shocks to which a ship-of-war is necessarily exposed.

THE STUDY OF THUNDERSTORMS.—There still remains an immense amount of patient work to be done in the way of protracted and careful observation before the phenomena of thunderstorms can receive anything like complete elucidation. Dr. Hann, of Vienna, has recently contributed a valuable monograph upon this subject. From a study of thirty-two years' observation of thunderstorms in the Vienna region Dr. Hann finds that there is a double maximum of frequency. The greatest number occur in the first half of June, the second smaller maximum is in the end of July; between these is a secondary minimum. (Thunderstorms hardly ever occur in winter.) This agrees with observations in Munich. In Brussels most thunderstorms occur in the second halves of June and July. The daily period in Vienna shows a chief maximum about 3:20 p.m., and a secondary one at 1:20 a.m. The spring and summer storms come mostly from the east and south-east, and seem to belong to Mediterranean depressions, coming up from the Adriatic, as those of late summer seem to be on the south or south-east border of Atlantic depressions.

A NEW ARC LAMP-POST.—In designing an arc lamp-post for street lighting, it is desirable to endeavour to combine economy with maximum height and strength, and also, if possible, to arrange for the replacement of carbons, adjustment, cleaning, &c., to be performed from the street level. If we were also expressly desired to leave out of view the most elementary considerations as to sightliness, we might further take into account the fact that the street would be much better illuminated if the lamp was suspended over the centre of the roadway. We should then very probably arrive at a form of post very similar to that recently introduced by one of the American electric light companies. This consists of an upright post bearing a horizontal cross bar pivoted at its upper part. The longer arm of the cross bar projects over the centre of the roadway and carries the lamp, the shorter arm is provided with a counterpoise. By means of a lever attached to this arm the cross bar can be tilted until the lamp reaches the level of the ground. No mere verbal description can do justice to the hideousness of the design.

OPPOSITION TO THE BELL COMPANY IN AMERICA.—It is stated that a powerful syndicate is about to be formed, in order to endeavour to break down the telephone monopoly in the States, by the introduction of an instrument invented by Messrs. Dann and Lapp, which is alleged to work by make-and-break, and not by alternating currents. It is proposed to commence operations at Rochester, where, as we recently mentioned, a feud exists between the local Bell Company and their clients, and has resulted in the withdrawal of 600 out of 700 subscriptions. Meanwhile we learn that Rochester merchants placard their telephones with sarcastic mottoes, and

Digitized by Google

the local telegraph companies find it necessary to double their staffs. With regard to the theory of a make-and-break telephone, it is obvious that unless special care is taken to avoid all self-induction in the circuit, however abrupt the make-and-break may be in the transmitter, the current in the receiver will still be of an undulatory character. We trust, however, that this observation will not have any influence upon the decision of the law courts, to which an appeal will undoubtedly be made directly the new company commences active operations.

OFFICIAL REPORT OF THE VIENNA EXHIBITION.—The official record of the tests of the electrical section of the Vienna International Exhibition of 1883 has just made its appearance in the form of a bulky octavo volume. The tests themselves were of an almost exhaustive character, and undoubtedly reached a very high standard of accuracy; it is therefore the more to be regretted that the delay of nearly three years in their publication should deprive them of almost every interest, save that of a historical character. From the latter point of view, it is, however, of considerable value to have such excellent authority for the statement that in 1883 the highest commercial efficiency yet attained in the construction of dynamos did not exceed 78 per cent., while in quite the majority of machines tested it ranged between 50 and 65 per cent. The tests recorded in the volume comprise a very wide field of investigation, including measurements of power obtained from various engines, the calibration of mechanical dynamometers, tests of glow and arc lamps, accumulators, efficiency of dynamos, primary batteries, thermopiles, conductors, and the transmission of energy. It is a pity that a good index has not been added, which would have much enhanced its value as a work of reference.

PROPOSED ELECTRIC TRANSMISSION OF POWER IN CEYLON.—The *Indian Engineer* states that the application of water power in the planting districts is attracting much attention in Ceylon, where the electric transmission of power for tea factories is likely in future to have an extensive field. It appears that some local tramway company is anxious to obtain information upon the subject, but our contemporary does not mention the locality. In other parts of India the advantages of electric transmission are being canvassed with much interest, and at Bombay the local journals are seriously discussing the possibility of utilising tidal power for the charge of accumulators. We should be sorry to say anything to discourage the idea of utilising the forces of nature to their fullest possible extent, especially in such a country as India. As the *Bombay Gazette* puts it, "With coal at 11s. a ton, as in England, steam may be justifiable, but when coal has to be brought thousands of miles at an enormous expense, it is time that the scientific imaginations of our citizens were set at work to see if a cheaper substitute cannot be got for it." At the same time it is as well to remember that it has never as yet been found practicable to employ tidal force with any economical advantage. On the other hand, the water courses of India will in many districts afford magnificent opportunities for the electric transmission of power.

TONQUIN.—NATIVE IMPROVEMENTS IN TELEGRAPHY.—An extract from a private letter received from a lieutenant in the French Army of Occupation in Tonquin gives an amusing account of the difficulties which have to be encountered in the maintenance of the telegraph lines in that country. On one occasion communication between Hanoi and Haiphong was totally interrupted, and several days elapsed before the locality of the fault could be detected. At length, after traversing the whole length of the line without discovering the fault, the officer in charge observed upon his way back that in the neighbourhood of one of the villages of a friendly tribe the line seemed rather thicker than elsewhere, and on a closer inspection it was discovered that several miles of wire had been removed, and had been carefully and neatly replaced with bamboo rope. The headman of the village explained that iron wire was a valuable commodity in his district, but that as a proof of his affection for the French he had issued the most stringent orders that whenever any wire was removed from the line, repairs were immediately to be effected in the manner described. The officer attempted to explain the difference between conductors and non-conductors of electricity, but eventually found it more to the purpose to intimate that any future supplies of bamboo rope for telegraphic purposes would be utilised for the summary execution of the nearest head man.

CENTRAL STATION LIGHTING AT ROME.—The *Bulletin Internationale de L'Electricité* contains a long account of the central lighting station at Rome which has been established by the Anglo-Roman Gas Company, and is worked with alternating currents and Gaulard-Gibbs transformers connected in parallel. The installation at present comprises 24 arcs of 800 candles for street lighting, and 600 Edison lamps of 16 candle-power, of which the greater number are distributed in three or four large buildings. The name of the makers of the alternating machines is not given, but from some of the details they would appear to be Ganz dynamos. There are two machines, each giving 2,000 volts and 42 amperes. The speed is not given, but the engine from which they are driven is said to run at 250 revolutions and to work up to 150 horse-power. Only one of the dynamos is at present in use, the other being held in reserve. The conductors are placed underground, their total length being nearly four miles. The fittings have been paid for in each case by the consumers, and the charge for current is made at the rate of 80 centimes per hour for each arc, and 8 centimes per hour for each incandescent lamp. A very large extension of the installation is projected, and was in fact provided for in the erection of the buildings where the engines and machines are placed. If the present scheme is carried out the installation will become one of the most important in Europe, and will have a capacity of over 18,000 glow lamps. It is proposed to employ four large machines each capable of supplying 4,000 lamps, and two smaller machines with a capacity of 1,000 lamps, together with three continuous current dynamos for exciting the fields. The total motive power to be provided, including spare engines, will exceed 2,500 horse-power.

MR. BROWN ON THE SEAT OF ELECTROMOTIVE FORCE.—In a paper recently read before the Royal Society on "A Theory of Voltaic Action," Mr. J. Brown expressed the opinion that the difference of potential near two metals in contact is due to the chemical action of a film of condensed vapour or gas on their surfaces. Such a pair of metals is thus similar to a galvanic cell with its electrolyte divided by a diaphragm of air or other gas, and it is the difference of potential of the films that is measured in "contact" experiments; the metals themselves being at one potential. But it appears that covering the metals with varnish, or immersing them in naphtha to protect them from atmospheric action, reduced the difference of potential near them considerably, but not to zero. Drying the atmosphere about a copper-zinc pair by means of phosphoric anhydride in one instance reduced the difference of potential in 173 days from ·66 to ·5 Daniell. Then, on opening the instrument, it rose to ·67 Daniell. Experiments with an electrometer having quadrants of the metals under examination were made on the rate of decrease on the differ-

Digitized by Google

ence of potential near two metals in contact, and exposed to the action of the air and of other gases; also where a change in the constituents of the atmosphere surrounding a pair of metals in contact reverses the difference of potential near them in correspondence with the reversal of electromotive force which takes place after a similar change in the corresponding liquid electrolyte used with the same metals as a voltaic cell. Such reversal takes place with pairs of copper-iron when hydrogen sulphide gas, or ammonia gas, is added to the air surrounding them; with silver-iron when hydrogen sulphide is added; and with copper-nickel when either ammonia or hydrochloric acid gas is added.

LIFEBOATS AND ELECTRICITY.—In the course of a leading article upon the recent disastrous loss of lifeboat crews, *The Times* of yesterday suggests that electricity might be made available as a motive power for lifeboat service. "Accumulators," thinks *The Times*, "might possibly be fixed so as to form a portion of the ballast." Certainly they might, though as ballast they would be somewhat expensive, and for any other purpose storage batteries would be utterly out of place in a lifeboat. It is decidedly unfortunate that the leading English journal should entertain such hazy ideas upon a matter of this character. Apart from such fundamental objections as to the impossibility of keeping the cells always in a condition for active service at a moment's notice, we doubt whether any makers of accumulators would be prepared to supply cells guaranteed to stand the amount of knocking about which must be undergone in such service. *The Times* is possibly unaware that accumulator cells cannot be hermetically sealed up. In this connection we may, however, mention that, notwithstanding this difficulty, the E.P.S. Company, after very numerous experiments, have recently succeeded in designing a form of cell which will bear repeated and rapid inversion without serious loss of liquid. In this case, however, the application is only upon a small scale, and any failure of action would tend to the preservation rather than the destruction of human life—that is to say, the cells were designed for use upon a self-propelling torpedo, which will shortly be brought out by Mr. Nordenfelt. One of the boats which capsized off Southsea made a voyage of 12 miles out to the vessel. We should be glad to get some idea of the power required to propel a boat with a crew of twelve men at the rate, say, of 10 or 12 knots an hour through a storm such as that of the 6th inst.

THE SNOWSTORM AND OUR LINES TO THE CONTINENT.—The *Standard's* Berlin correspondent states that the *National Zeitung* charges the English authorities with culpable negligence in connection with the existing interruption of telegraphic communication between England and the Continent. While in Germany, thanks to the subterranean lines, the wires are all in full operation down to the submarine cables, London is entirely isolated, owing to the indolent indifference of the British Government, which has failed to adopt the precautions which have for years proved so efficient in Germany. The *National* continues:—"Since Monday morning all telegraphic communication with England *viâ* Emden, Amsterdam, Brussels, Paris, and even *viâ* Friedericia and Arendal, has been interrupted by severe snowstorms, an interruption that causes loud and well-grounded complaints on the part of the public. The French cable ends at Dover, and the German at Lowestoft. The German subterranean is acting perfectly, in spite of the ordeal it has recently gone through. On inquiry in competent quarters we hear that all the telegrams from here to London, *viâ* Brussels, are sent by wire only to Ostend, whence they are transmitted to Dover by steamer, thus causing a delay of twenty-four hours. The cable from Ostend to Dover cannot be damaged, because this would otherwise have been notified; hence it is only the short terrestrial wire from the sea cable to the cable house at Dover that can be disturbed. This interruption, which most sensibly affects all commercial business, as well as political and social life, is due not to *force majeure*, but to the negligence of the English. Every violent storm, so often beating on England's southern coast, disturbs this short non-subterranean wire from the cable to the first office. Complaints have already been made times without number, but all in vain, owing to English red-tape. The line from Lowestoft to London is neither long nor technically difficult to keep in order. The English Government will be compelled in the end seriously to take the matter in hand, and to lay down a subterranean cable on that line. Its present condition is a source of vexation to the whole of Europe."

REMARKABLE METEOROLOGICAL PHENOMENON IN VENEZUELA.—The United States consul at Maracaibo, Venezuela, has furnished the following account of what he terms an "electrical eccentricity:"—"During the night of the 24th of October last, which was rainy and tempestuous, a family of nine persons, sleeping in a hut a few leagues from Maracaibo, were awakened by a loud humming noise and a vivid, dazzling light, which brilliantly illuminated the interior of the house. The occupants, completely terror-stricken, and believing, as they relate, that the end of the world had come, threw themselves on their knees and commenced to pray, but their devotions were almost immediately interrupted by violent vomitings, and extensive swellings commenced to appear in the upper part of their bodies, this being particularly noticeable about the face and lips. It is to be noted that the brilliant light was not accompanied by a sensation of heat, although there was a smoky appearance and a peculiar smell. The next morning the swellings had subsided, leaving upon the face and body large black blotches. No special pain was felt until the ninth day, when the skin peeled off, and these blotches were transformed into virulent raw sores. The hair of the head fell off upon the side which happened to be underneath when the phenomenon occurred, the same side of the body being, in all nine cases, the more seriously injured. The remarkable part of the occurrence is that the house was uninjured, all doors and windows being closed at the time. No trace of lightning could afterwards be observed in any part of the building, and all the sufferers unite in saying that there was no detonation, but only the loud humming already mentioned. Another curious attendant circumstance is that the trees around the house showed no signs of injury until the ninth day, when they suddenly withered, almost simultaneously with the development of the sores upon the bodies of the occupants of the house. This is perhaps a mere coincidence, but it is remarkable that the same susceptibility to electrical effects, with the same lapse of time, should be observed in both animal and vegetable organisms. I have visited the sufferers, who are now in one of the hospitals of this city; and, although their appearance is truly horrible, yet it is hoped that in no case will the injuries prove fatal."

SPECIFIC INDUCTIVE CAPACITY, RESISTANCE, AND RADIATION OF DIELECTRICS.—M. J. Currie has recently been engaged upon an important series of researches on the relation between the instantaneous specific inductive capacity, the conductibility, and the power of thermal absorption or radiation of dielectrics. In a note presented to the French Academy he has given a description of the methods employed, but we shall con-

Digitized by Google

tent ourselves for the present with a quotation from the latter part of the paper in which the results obtained are summarised. It will be seen that, so far as they go, these results accord with the theory of Clerk-Maxwell, and this circumstance is the more interesting in view of the negative results of Mr. Shelford Bidwell's recent experiments upon the connection between diathermancy and electrolytic conductivity. (See *Electrician*, Nov. 19, 1886, page 35). A very striking fact (says M. Currie) is the great constancy of the values obtained for the instantaneous specific inductive capacity with the extreme variability of the values of the conducting power or resistance. All the different samples of the same substance (cut in the same direction for crystalline bodies) yielded the same values for the former quantity. It is, on the contrary, impossible to find any two samples giving identical results as regards specific resistance. It is not uncommon to find two plates of the same substance, apparently equally pure, which show values differing in the ratio of 5 to 1. Variation of temperature has little influence upon specific inductive capacity, but it has an enormous effect upon the conductivity, and upon cooling the resistance frequently does not regain its original value. In spite, however, of these causes of uncertainty, the relative conductivity of many dielectrics may be considered to be known with tolerable precision, because at the same temperature they often differ enormously from one another. For instance, the resistance of rock salt is about 10,000 times higher than that of glass. A perfect dielectric would be one which after an instantaneous charge would yield no current. All the substances (here examined) tend towards this condition as the temperature is lowered. M. Boltzmann has shown that crystallised sulphur is a very perfect dielectric. This research has shown that for moderate temperatures we may place both rock salt and fluor spar in the same category. As good dielectrics we have quartz (cut parallel to the optic axis), topaz (in planes of cleavage), mica, and ebonite. Lower down the scale we have the following bodies in the order named:—Iceland spar (perpendicular to the optic axis), quartz (in the same direction), sulphate of barium (in planes of cleavage), rose tourmaline, green tourmaline, alum, glass. Now it is interesting to compare the list here given with that of the same substances as placed by Melloni in the order of their absorbing and radiating powers:—Rock salt, sulphur, fluor spar, Iceland spar, quartz, glass, white topaz, sulphate of barium, tourmaline (dark green), alum. In a general sense, the relation indicated by Clerk-Maxwell between the conductibility and the absorbing power seems here to be verified. It is at least certain that the three most perfect dielectrics, rock salt, sulphur, and fluor spar, are also the three most diathermanous substances known. We may remark also that ebonite, which is one of the worst conductors, has been shown by Prof. Bell and Capt. Abney to be an excellent transmitter of radiant heat. We can scarcely yet affirm, however, that Maxwell's theory has received complete experimental demonstration in this particular, and, in fact, in the present state of our knowledge it would be almost impossible to obtain a precise verification, since, on the one hand, the strength of the current through a thin plate of a dielectric is a function of the time, and, on the other hand, the absorbing power depends on the length of the undulations of the heat waves. The figures given by Melloni correspond to an ill-defined group of radiations.

ROYAL COMMISSION ON THE TELEGRAPH SYSTEM.—The Royal Commissioners on Civil Establishments having suggested to the Postmaster-General that if the members of any particular class or classes desire to be heard specially by the Commissioners upon any matter within the terms of the Commission they should be at liberty to select representatives to give independent evidence. This suggestion the Postmaster-General falls in with, and has intimated to the telegraphists that if they wish to be examined by the Commissioners they should write direct to the secretary. This permission was expected, and in view of it meetings have been held in the principal towns to confer as to the evidence which might be required, and to appoint committees to collect and tabulate it. Circulars have been printed and sent to the various telegraph centres by the Telegraph Clerks' Association, asking for information on the various points which it is thought likely the Commission may inquire into. The telegraphists have decided to submit evidence bearing on salaries, which are alleged to be inadequate; on hours of labour, which are believed to be excessive, considering the tremendous strain on the nervous system of eight hours' continuous telegraphing; on annual leave; on the cost of staff; and on the administration and organisation of the telegraph system. It is stated that under the existing scales of pay—which were adopted by the late Mr. Fawcett in 1881, after a good deal of agitation carried on energetically by the telegraph clerks—it takes some fifteen years to attain the maximum salary of the lowest class, the pay being about equal to that of a mechanic. Promotion to the higher class is alleged to be very unsatisfactory. At Leeds, according to the *Telegraphist*, the senior second-class man has twenty-three years' service, and the man under him has twenty years; while at Sheffield, the same journal states, the senior second-class man joined in 1862, so that with 24 years' service he has only 38s. a week. The telegraphists intend to call the Commissioners' attention to the great difference in value of the superior appointments in the Postal as compared with the Telegraph Department. It is believed that no difficulty will be found in proving that the hours of duty—which are eight per diem—are too long. It is stated that evidence will be forthcoming that the sick-rate in the telegraph as compared with other departments is excessive, and that in recent years many superannuation allowances have been granted to clerks whose nervous systems have been completely shattered by the severe strain, and it is expected medical opinions will be submitted in support of these allegations. With regard to the cost and administration of the service, they state that the opinion of practical telegraphists should be of considerable importance. The telegraph vote for the current year is about £1,800,000, and something like 30 per cent. of this goes to the accounts department, while £41,000 is given to the secretary's offices. It is thought that by strict economy the accounts might be kept at a very much smaller expenditure. The telegraphists are anxious to see an alteration made in the organisation, by which it is hoped a saving will be effected in the pension list. They suggest that as it is admitted that telegraphists after 20 years' service are played out as operators, though as good as ever for ordinary clerical labour, the higher appointments in the Postal and Telegraph Departments, which presently are filled by youths who have passed the examination for the lower division, should be given to the senior telegraph clerks, thus removing them from the trying duties of a telegraph office, and for which they are no longer fit, before the inevitable break-down. If this were done the public would benefit by a reduced pension list and by better telegraphic service, while the higher branches would obtain the services of clerks who had gained a considerable and varied experience, which could not fail to be beneficial to the department to which they were transferred; besides, it would materially improve the flow of promotion in the telegraphs, the stagnation of which is a fruitful source of agitation.—*Glasgow Herald.*

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 143.)

[ERRATUM.—In the 21st line from bottom of column 1, page 142, of our last week's issue, *for* "arc lamps of 1,000 candle-power" *read* "arc lamps of 2,000 candle-power."]

It should be noticed that the opposing E.M.F. is independent of the strength of the battery urging the current, and would, therefore, be the same even if there were no battery. In the case we have considered the number of lines of force passing downwards through the circuit is increased, and the induced electromotive force is in the direction, east, north, west, south, so that the direction of the electromotive force is negative with respect to the lines of magnetic force. The same form of proof would also apply if the lines of force were cut at any angle instead of orthogonally. Hence we have the general law:—

When a conductor moves in a magnetic field an electromotive force is induced, represented by the *rate of diminution* of the number of magnetic lines of force passing through the circuit in a positive direction.

Lenz indicated the direction of the induced electromotive force by saying that

When a conductor moves in a magnetic field an electromotive force is induced, which tends to produce a current, which by its electromagnetic action would oppose the motion of a conductor.

This statement is known as Lenz's law.

If two coils of wire are placed near together and so as to be co-axial, and if a current be started in one coil, the lines of force due to the current will pass through that coil in the positive direction, and some of them will pass through the other coil in the same direction. Hence there will be a current induced in the second coil opposite in direction to that started in the first. On stopping the current in the first coil a current will be induced in the second in the same direction as that in the first, and will last until the primary current has died away.

Whenever the number of lines of force passing through a circuit is altered, whether by the motion of the circuit or of magnets or of other conductors conveying currents, or by the starting, stopping, or variation of currents in other conductors, there will be an electromotive force induced in the coil represented by the rate of diminution of the lines of force passing through the circuit in the positive direction; that is to say, if the number of lines of force passing through the circuit be increased the electromotive force will be in the negative direction with respect to them, while, if the number of lines of force be diminished, the electromotive force will be in the positive direction.

If lines of force pass vertically downwards, and a wire running east and west and forming part of a closed circuit be moved from south to north, a current will be induced in the wire from east to west, while a mechanical force will act upon the wire, urging it from north to south—that is, opposing its motion.

It is at first sight, perhaps, not easy to see the connection between the generation of a current by the cutting of lines of magnetic force through the motion of a conductor, and by the starting or cessation, increase or decrease, of a current in the neighbourhood of a conductor. The law that the electromotive force in a conductor is represented by the rate at which it cuts lines of force is equally applicable to all cases. Were it possible to generate instantaneously a current in a wire in the neighbourhood of a closed circuit, then a finite number of lines of force would, generally, be projected through the closed circuit in an indefinitely short time, and the *rate* of change of the number of lines of force passing through the circuit, and with it the electromotive force and induced current in the circuit would be infinite. But such a sudden generation of a current is impossible; in fact, its inductive action in its own circuit alone will limit its rate of increase. We must therefore remember that the generation or cessation of a current takes place by a continuous change occupying a finite time. Suppose A and B to be two wires, and a current to be started in A, while B is a portion of a closed circuit. At first the current in A will be indefinitely small, and its magnetic action will be distinguishable only very close to the wire. We may suppose that after a little one line of force drawn round the wire represents the whole of the magnet field. As the strength of the current in A increases this line of force will expand, and new lines of force will spring into existence around the wire, themselves expanding as the current is increased. One after another these lines of force cut across the wire B, causing a current to be induced in its circuit, the electromotive force in B being proportional to the rate at which these lines of force cut the conductor—that is, to the rate at which the current in A increases. Thus the effect upon B of an increasing current in A is exactly the same as though the wire B were moved across certain of the lines of magnetic force due to A. Sometimes in considering adjacent coils of wire we speak of the lines of force of the current in one coil as being projected through the other coil. If, however, we remember that the lines of force are all closed curves, that they originate close to the primary wire, gradually expanding as the current increases, we see that every line of force which passes once through a closed circuit must, in coming into this position, have cut the circuit itself. Suppose, for instance, that there are two coils A and B, and that when a current, C, flows in A there are n lines of force, due to this current, passing through B. If there be no current in A initially there will be no lines of force passing through B, due to the coil A. As the current in A gradually increases the lines of force due to the current in A will gradually expand, and one after another will cut the coil B until, at length, when the current C has been established in A, there will be n lines of force, due to this current which have cut the coil B and are passing through it. The result is the same, whether the current C take a long time to develop, or whether it be started in a time too short to be estimated. If the coil B contains m turns of wire, then each of the n lines of force cuts m wires, and the effect is the same as though $n\,m$ lines of force had cut or been cut by one wire. If the current C in the coil A be generated at a uniform rate, increasing from zero to its full value in one second, then $n\,m$ will represent the steady electromotive force induced in B during that second, the electromotive force being in the negative direction with reference to the lines of magnetic force. If a unit current in A causes $n\,m$ lines of force to pass through B, then $n\,m$ is called the coefficient of mutual induction of A and B, and it may be shown that a unit current in B would cause the same number of lines of force to pass through A. If a unit current be uniformly generated in the coil A, so as to increase from zero to its full value in one second, the electromotive force induced in B will be numerically equal to the coefficient of mutual induction of A and B.

If a current C is generated in a coil, A, at a uniform rate, so as to be increased from zero to its full value in t seconds, and if M be the coefficient of mutual induction between A and B, the electromotive force in B will be represented by $\frac{MC}{t}$, and if R denote the resistance of the circuit B, the current in it will be $\frac{MC}{Rt}$, and the whole amount of electricity which passes any section of the conductor B while the induced electromotive and current last—that is, during t seconds—will be $\frac{MC}{R}$. Now, MC represents the whole number of lines of force passing through B on account of the current C in A. Hence we see that the whole amount of electricity which passes through a secondary coil during the production or cessation of a current in the primary, is equal to the whole number of lines of force which pass through the secondary coil when the current in the primary has its maximum value, divided by the resistance of the secondary circuit.

Thus, while the electromotive force in the secondary circuit depends on the *rate of change* of the primary current, the whole amount of electricity passing through the secondary circuit depends on the whole change taking place in the primary and not on its rate. A good example of this is afforded by the Ruhmkorff coil. In this coil contrivances are introduced which enable the primary current to be stopped in an extremely

Digitized by Google

short interval, while a very much longer period is required for its generation. Consequently the electromotive force in the secondary coil is very great indeed when the primary circuit is interrupted, but when the primary current is again started, the electromotive force in the secondary is comparatively feeble, and not sufficient to break through the air space generally left between the terminals of the secondary coil. Thus we get a spark at the "break" but none at the "make." If, however, the secondary circuit consist wholly of metal, so that Ohm's law is obeyed throughout, the induced current at the "break" will be very strong and of short duration; that at the "make" will be much feebler, but will continue for a proportionately longer time, and the whole amount of electricity passing through the circuit will be the same in the two currents. This result affords a good experimental proof of the truth of Ohm's law, for it shows that what has been called the resistance of the secondary circuit is the same, whether the electromotive force be very great indeed or comparatively feeble, and this is, as has been explained, the essential feature of Ohm's law.

The first observed phenomenon which depends upon electromagnetic induction was exhibited by the experiment of Arago's disc. A magnet was suspended horizontally, with its centre a little above that of a circular plate of copper. The copper disc was made to rotate rapidly, and a plate of glass introduced between the disc and the magnet to get rid of the effect of currents of air. Notwithstanding this precaution, the magnet was made to rotate, and to follow the disc. The experiment was repeated by Sir John Herschel and Mr. Babbage, and discs of various materials were tried, but only those which were good conductors of electricity produced any effect. No explanation satisfactory to Arago himself was offered until the experiments of Faraday developed, in the course of a few months, the laws of electro-magnetic induction which have been given above, and laid the foundation for the the introduction of the telephone, the magneto-electric machine, and the "dynamo."

In Faraday's earliest experiments he endeavoured to obtain a permanent current in one coil through the influence of a permanent current in a neighbouring coil, in accordance with the analogy of a permanent state of electrification produced in a conductor by the neighbourhood of a charged body, but his most delicate galvanometers failed to show any sign of a current when connected to the secondary coil. After repeated failures, and upon returning to the experiment after an interval of some years, Faraday, in 1831, observed an instantaneous deflection of the galvanometer connected with the secondary coil when the current was started or stopped in the primary. This put Faraday on the right tack, and his imaginative mind enabling him to see every magnetic field filled with magnetic lines of force, these served to guide him in his experiments, and in a few months he appeared to have investigated the whole of the subject of electromagnetic induction. Winding two coils of wire upon a ring of iron, and connecting one coil with a battery, the other furnished strong currents when the primary circuit was made or broken, the iron serving to conduct the lines of force from the one coil through the other. Winding a coil of wire around an iron bar, the ends were attached to two stout pieces of wire, one of which carried an amalgamated copper disc, while the other terminated in a point which just touched the disc. On letting the iron bar fall through a short distance upon the poles of a magnet, the shock caused the disc to separate from the point, while the induction current due to the sudden projection of the lines of force of the magnet through the centre of the coil was flowing. This caused a spark to leap between the disc and the point, and thus an electric spark was obtained from a magnet. The same result ensues whether the magnet be a permanent magnet or an electromagnet.

Faraday's investigations at once explained the experiment with Arago's disc. As the copper plate rotated it cut the lines of force, which diverged from the north pole or converged to the south pole of the magnet. This caused a current to flow along the diameter of the disc which was parallel to the magnet, the current returning by the circumferential portions of the disc. This current produced a mechanical stress between the disc and magnet tending to destroy the relative motion, and since the disc was compelled to turn the magnet was drawn after it. Faraday caused a copper disc to rotate between the poles of the magnet, a contact being made with the disc at its centre, and a second contact made by a spring pressing against the circumference of the disc at the extremity of the radius which passed between the poles of the magnet. A galvanometer being connected with the contact pieces, a current flowed through the circuit when the disc was made to rotate.

(To be continued.)

CORRESPONDENCE.

UNCOMMON MISTAKES IN ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: At this festive season I beg to propose the following puzzles or conundrums to your juvenile readers:—

1. Why will not iron filings stick to the sides of a uniformly and longitudinally magnetised bar? (See *Electrician*, page 7, Nov. 12.)
2. What connection has the last with the question about the fish propounded by King Charles to the Royal Society?
3. Has *superficial* magnetism anything to do with the phenomenon?—Yours, &c., O. H.

RETORT CARBON PATENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My attention has been drawn to a paragraph in a paper by Mr. Swinburne on "Retort Carbon," which appeared in a recent issue of your paper.

Mr. Swinburne speaks of patents taken out and researches made by Messrs. Hughes, Rowland, Maxwell, and Chambers.

The Maxwell patent has nothing to do with retort carbon, and the only patent which I know of on the subject was taken out as the result of the joint work of Mr. Hughes and myself.—Yours, &c., ROLAND CHAMBERS.

December 29th, 1886.

LITERATURE.

The Gas Engine. By DUGALD CLERKE. (London: Longmans, Green and Co., 1886, pp. 279).

In a small handy book Mr. Clerke has succeeded in presenting to the world the best treatise yet existing on the gas engine.

Until within about five years very little was generally understood of the complex thermo-dynamics of the gas engine, but since that time several very able writers have devoted themselves to the elucidation of what was theoretically in a very unsatisfactory position. Gas engines, like other motors, had been made by practical men with a little or with no real knowledge of the actual behaviour of explosive or combustible mixtures in a closed vessel, and these men had gradually developed the engine until a good practical machine had been produced. More theoretical knowledge has been at the disposal of the most recent workers in this line, for with a practical success to provide information, scientific men have been able to systematise the facts presented, and by some experiments on moot points, to place before those interested in gas engines some of their ideas as to what was wanted, and to show that theoretically there were deficiencies which the practical man might, if he chose, grapple with until he stumbled upon the best means of removing them. Mr. Clerke is, however, one of those who have not only done as much, or more, than any other investigator and writer to present useful theory to the world on the complex problems involved in the construction and working of a gas engine, but he has produced an engine which has achieved very high efficiency, so high that one of his twelve-horse engines has given an indicated horse-power for a little over 20 cubic feet of

Digitized by Google

gas per hour. He has been experimenting since 1876, and has in the ten years which have passed between then and the publication of his book acquired a more intimate knowledge of the gas engine in theory and practice than any other writer, and this has enabled him to appreciate the requirements of those who are most in want of a good book on the subject.

His first chapter is historical, and in this the history is of that kind which may be described as strictly technical as compared with anything apart from the gas engine itself and its development, or with anything personal to the several inventors. He is very careful to bestow credit where credit is due, and his praise of Herr Otto's inventions is noteworthy. His second chapter is on "the gas engine method," and may be looked upon as introductory to the third chapter, which is on "the thermo-dynamics of the gas engine." It relates to the method of heating and using the working fluid, the peculiarity of the gas engine being that the fuel and the working fluid are introduced into the motive cylinder and the fuel burned therein. It is to this method that the gas engine owes its great actual efficiency and its potential efficiency through the high temperature or high range of temperature which may be employed. He points out the steps in this respect which have led to the present engine. In the second chapter gas engines are classified, the classification being the same as that adopted by the author in his paper read before the Institution of Civil Engineers.* The first of the three classes is that including engines igniting at constant volume, but without previous compression, a type of which the Lenoir, the Hugon, and Bisschof are examples. The second type is of engines igniting at constant pressure with previous compression, and the third type includes the engines in which ignition takes place at constant volume with previous compression. The Brayton and the Simon and Simon Beechy and one of Atkinson's engines are the best known of the second type, and the Otto, Clerke, Tangye (Robson's), and Stockport (Andrews), and Atkinson differential are the best known, in the order given, of the third type. The author explains the classification and recalls attention to the earlier publication of the elements of the more modern engines in each type, and especially of the third type, which was very minutely set forth by Beau de Rochas in 1860 and by M. F. Million in the same year, though Otto was, as he admits, the first to apply the leading idea as set forth by these two, but not until 1876. The thermo-dynamic consideration of the gas engine leads now, as it did at the time of the author's paper already mentioned, to the conclusion that its efficiency depends upon the ratio between the initial temperature and the temperature of the adiabatic compression of the charge, and the temperature of the explosion may be any temperature greater than that without altering the efficiency. Dr. A. Witz published a very useful explanatory paper on the thermo-dynamics of the gas engine in the *Annales de Chimie Physique*, in 1883, an abstract of which appeared in the *Proceedings* of the Institution of Civil Engineers,† but Mr. Clerke points out what has apparently been overlooked, namely, that Dr. Witz assumed that the expansion of the gases after explosion expanded adiabatically as well as that they were compressed adiabatically, an error which needs only to be pointed out. The causes of loss in gas engines occupy the fourth chapter. These are examined as by one who is most anxious to find out every cause of loss with a view to improvements, and the examination is of a practical character, and many of the points involved lead directly to the details of the subjects of the next two chapters—namely, those on combustion and explosion, and on explosion in closed vessels. Upon both these questions Mr. Clerke has added more to our practical knowledge than perhaps any other investigator, and for the results we will refer to his little book.

In it he describes his apparatus and gives the curves obtained with various mixtures of different gases, showing pressures, rate of combustion, and temperatures, and thereby the best mixtures for engines of the different types. The gas engines of the different types in practice, the igniting arrangements, and other mechanical details occupy the next chapters, and these are followed by a chapter on "The Theories of the Action of the Gases in the Modern Gas Engine." In this chapter the author very cleverly discusses the theories as they have been expounded by Dr. Otto and by the several scientific men in England who support the almost absurd notion concerning the stratification of the charge in a gas engine cylinder even after compression, and no one can deny that Mr. Clerke has very fairly put all the best of the arguments of this school, and has equally well met them, and has thoroughly refuted them. In fact, if our patent law cases could be tried by a technical jury of a high class, the gas engine would never have been the subject of so much biassed statement as it has been, on more than one occasion important in the annals of invention and patent laws. In the chapter on the future of the gas engine Mr. Clerke gives a few indications which may be new to some, but most have probably been long seen by those best acquainted with this motor. He mentions some points of a thermo-dynamic order which are well worthy of close attention.

Mr. Clerke's book is clear and well arranged, and should be in the hands of everyone interested in the subject of gas engines.

ELECTRICAL WELDING.

At the meeting of the American Society of Arts, on December 9th, Prof. Elihu Thomson, of the Thomson-Houston Electric Light Company, read a paper on the subject of the "New Art of Electric Welding." The apparatus was shown in working order. One of the largest lecture rooms in the rear of the new building of the Massachusetts Institute of Technology was filled by about five hundred interested spectators. The following is the substance of Prof. Thomson's paper :—

In the past 15 years there has been a great expansion of the uses of electricity in the arts, the telephone, transmission of electric current for light and power. Of these, perhaps, in the future the transmission of power will be the most important. The energy of an electric current may produce mass motion (transmission of power), wave motion (telephony), light, chemical decomposition, and heat motion, which usually appears with the other transformations. The employment of heat generated by an electric current for the warming of buildings does not seem to be practicable ; the steam engine is so poor a converter of heat motion into mass motion that the efficiency of such a system would be very low. But in the arts where the amount of heat needed is small, or for sudden effects, or for high temperatures which are limited only by the vaporising point of carbon, heat produced by an electric current may be advantageously employed. An example of its successful employment is the Cowles electric furnace, in which the most refractory ores are reduced and metallic aluminium, boron, and silicon obtained directly from their compounds. In the dictionary definition of welding mention is made of the fact that tortoise shell could be easily welded. The lecturer remarked that he did not intend to experiment on tortoise shell. By the processes in common use it is difficult, if not impossible in many cases, to weld together different metals. Two pieces of the same kind of cast iron, zinc, tin, brass, and especially copper, have not been easily welded. By means of electricity they may be easily united. Iron, steel, and platinum, which have been the metals hitherto most easily welded, are by the new process still more readily united. To attempt by the new process to weld unlike metals may fail on account of a great difference in their temperatures of softening, or of their specific electrical and heat conducting capacities. The method is to forcibly press together two pieces to be united while passing a large current.

The method may be employed for joining into one continuous length short pieces of copper and iron wire. In the factory of the Thomson-Houston Company all joints in copper and iron wire are made in this way. The largest copper rod yet welded is a little less than ½in. diameter, requiring about 20,000 amperes. The same current will weld iron 1in. diameter, the difference in the size of the two metals being due to the greater resistance and lesser conductivity of iron. Specimens of various sizes, shapes, and materials were here shown ; cast iron, steel cast iron in one piece ; steel, brass, copper, also in one piece ; copper rod bent at joint after welding. Brazing can be done successfully by putting brass on a hot joint while current is passing. The smallest wires yet united by welding by this process have been $\frac{1}{50}$in. diameter.

Other specimens were butt welding of metal tubes, iron, brass, and copper, and lead. The iron pipes were hammered during the welding. Long lengths of cast or wrought iron pipe may be used in streets, a few bends being put in to allow for expansion and contraction. For making long lengths of pipes, for coils of pipe for boilers, and for other purposes, this method will be largely used, also for endless bands for saws, wheel tyres, tub, barrel, and tank hoops,

Digitized by Google

iron and steel links. There will be a wide use for the method in the repair of tools and parts of machines such as the following, some of which are put to practical use in the Thomson-Houston factory :— Lengthening of screws, taps, augers, lag screw bolts, by cutting off the shank and welding in a piece of iron or steel. A tool may be shortened by cutting out pieces and welding together. Steel points are welded to cast iron bodies of lathe tools; shafts may be lengthened. A carpenter's auger lengthened by this process was broken after being twisted two turns, the weld still being sound. For jewellers, as well as for others, this process may be made useful. Less fuel is required by the electric method of welding, on account of the small time required for the operation and the application of the heat locally, and the small losses from radiation and conduction. The time required being so short more joints may be made in the same time by comparatively unskilled labour.

In arc light circuits a current of 10 amperes, with an electrical pressure of 2,500 volts, is not infrequently employed. In incandescent lighting a current of 250 amperes, at an electrical pressure or electromotive force of 100 volts, would represent the same amount of electrical energy. In welding wire enormous currents are employed ; 50,000 amperes, at an electrical pressure of ½ volt, would represent exactly the same amount of electrical energy. This amount of current would probably weld steel 1½in. in diameter in less than two minutes. Electric lights demand a continuous application of power, while the welding, for instance, of a 1½in. piece of steel would require 35 horse-power for only one minute, the same power being required continuously to operate 40 to 45 arc lights.

The means for obtaining sufficiently large currents are two— storage batteries and alternate current machines connected with transformers. The coil, Fig. 1, is composed of a bundle of fine iron wires,

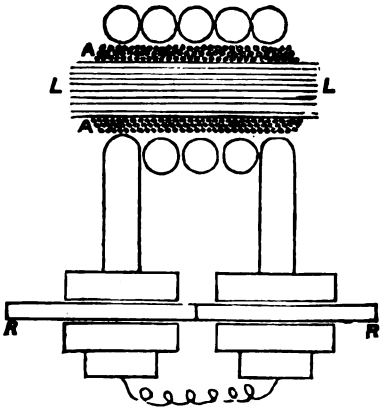

Fig. 1.

L L, around which are wound a number of layers of comparatively fine wire connected by the terminals A A to a source of alternating currents, a dynamo giving 50 to 100 alternations per second. The length of the iron core is 12in., the diameter about 1¼in. The secondary coil S S represented in the diagrams as composed of five turns of large copper, was in the smaller instrument shown composed of 64 No. 10 Brown and Sharp's gauge copper wires wound in parallel eight times around the primary. The ends were bolted to copper plates upon which the clamps are placed, one of which slides by an adjustable spring shown at the bottom of the diagram. By means of a cam the clamps may be separated to any extent. It takes only a few seconds to place the pieces of metal to be welded in the clamps. The iron core, on which the primary circuit is wound direct, may be pulled in and out. The power of the currents induced in the secondary coil is thus varied and adapted to any sized piece of forging. The resistance of the secondary coil is ·00015 ohm.

In the transformer or induction coil, illustrated in Fig. 2, the primary coil P P is a coil 12in. in diameter, 2½in. wide, and ¾in. thick, of many turns of insulated copper wire. The ends A A of this coil are connected with the alternating dynamo, and alternating currents thus pass through the wire of the primary coil. The secondary coil is a single heavy bar of copper bent to make one turn outside of the primary coil. The secondary is represented by the heavy black ring, the terminals of which, S S, are bent out to a parallel position and connected to massive screw clamps, M M. The secondary coil is shaped like a jew's harp. The parallel portions of this midway between S and M are made so that the clamp terminal M at the right may be moved. The screw C is used to force the terminals apart, the bars to be welded R R are clamped in position, the clamp C is unscrewed, and the tension of the spring D is adjusted by the screw attached to it. The pressure of the spring gives good contact of the bars R R. The primary and secondary coils are wound around with an endless coil of iron wire, I I I I. The iron wire does not touch the primary or secondary coils, but is wound on a sheet iron casing, the secondary coil thereby being free. The resistance of the secondary coil is ·00003, and under the influence of a good primary current gives an electromotive force of two volts ; less, however, is used in most cases. There is a small percentage of loss in the transformation ; a current of 20 amperes and 600 volts in the primary circuit gives in the secondary circuit nearly 1 volt and 12,000 amperes. To generate the alternating current an inexpensive dynamo is used, weighing 500lb., absorbing 25 horse-power at 1,800 revolutions per minute. There are 10lb. of copper wire on the armature, and 40lb. on the field-magnets. The large output from so small a machine without destruction comes from the fact that the machine gives current only for short intervals. There are suitable switches to stop the flow of current when the weld is complete. The primary circuit may be cut or the resistance in the circuit of the field-magnets of the dynamo may be varied, a method employed in the present case. To prevent overheating the primary coil of the machine illustrated in Fig. 1 may be pulled out to any extent, or resistance may be added to the primary circuit, or the strength of the field-magnets of the dynamo varied as described above.

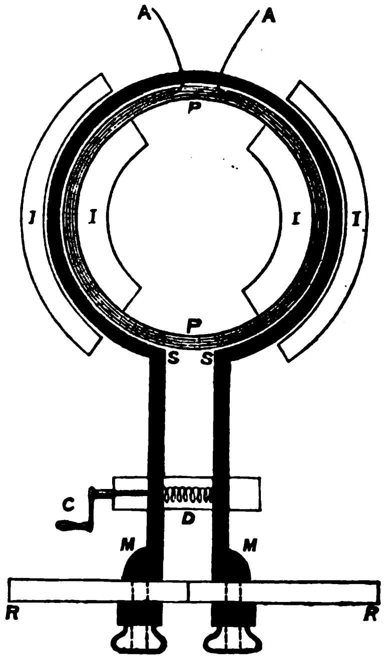

Fig. 2.

The ends of the pieces to be welded are brightened, and are allowed to project a little beyond the clamp when in position. A flux of some kind is now often put on the joint—powdered borax for metals that have a high melting point ; chloride of zinc, resin, or tallow for lead, zinc, and metals which have a low melting point. The current is now turned on, the ends of the rod become red, then white hot, and at the point of fusion soften ; the tension of the spring causes the joint to become upset or thickened. The current is shut off, the clamps unloosened, and the bar with the weld still red hot may be removed. Of course, many metals do not require even a red heat for fusion. In uniting a large to a small piece, the end of the large piece is first turned down to the size of the smaller. Sometimes the joints are hammered while in the clamps. It is probable that the result is caused by heat alone, though some electrical action may play a part. One circumstance tends to produce uniform heating of the abutting bars. Suppose one part of the surfaces is in much better contact than the rest. The larger part of the current will therefore flow in the path of least resistance. This part becomes hot, its resistance increases in consequence, and the current is to a large degree diverted to the colder portions of the joint, until the whole of the abutting surfaces are equally heated. There is no reason why cheap water power may not set in motion dynamos generating alternate currents of high electromotive force. Such currents may be transmitted with little loss over long distances, and by suitable transformers changed into currents suitable for welding. Accurate tests are to be made at once of the strength of the welds produced by this process. All practical tests applied thus far show that the joint is fully as strong as any other part. A lag screw, a portion in the centre of which was cut out, and the ends rather poorly welded without expansion of the joint, when turned into hard wood broke below the weld ; the break was sound. A penknife was shown, the two new blades of which had been welded to stumps projecting ⅛in., without removing them from the tortoise shell handle, which was not welded by the operation. In another knife a new blade, welded on by this process, was broken, but not at the weld.

LESSONS OF THE STORM.

The terrible storm of last Sunday night, although a subject of universal regret, is not to be passed over with the ordinary expressions of sympathy which visitations of that kind usually evoke. In the first place, injury to life and limb has been wonderfully small, the chief damage being confined to property, and this, too, not of private individuals, but of public companies and the State. Traffic has been greatly delayed on the railways owing mainly to the break down of electric signalling appliances, upon which our railway system has so long depended for its safe working. It was the electric telegraph that suffered most by the combined attacks of snow and hurricane, both in the metropolis and on the railways in its neighbourhood for many miles round. And the noticeable feature about this, as about the similar storm twelve months ago, was that, humanly speaking, those who have suffered are the people who deserve to suffer, whilst the unoffending people whose safety is continually jeopardised, in towns at least, by the overhead wires which are now lying about the streets in hopeless wreckage and confusion have miraculously escaped. This is a matter to be heartily thankful for; but the fact cannot be used as a proof of the safety of the system. Holiday time, Sunday, and the night, had fortunately emptied the streets. That is all that can be said. On Monday morning there was enough broken wire on the footways to have slaughtered a goodly number of victims had they been in the way instead of being in their beds. Travellers by night trains were not quite so fortunate; but here, again, there is a quite providential absence of serious accidents due to the falling of telegraph poles. The injury sustained is mostly of a pecuniary kind, and it will not fall upon the blameless.

What amount of actual damage has been done it would be difficult to estimate at present. Scarcely a railway line leading out of London has escaped with its telegraph poles and wires intact, and on the majority they have been wholly or nearly wholly disabled. Between Paddington and Didcot alone the broken poles number from two to three hundred; and on the Chatham and Dover and the South-Eastern railways the havoc to all appearance is not much less. The cost of re-erection will be very serious, the more so as in some instances the poles and wires had been renewed quite recently, and special precautions taken to ensure their stability. As a rule the telegraph poles, with their enormous burden of wires, are, in spite of their menacing appearance, beyond the reach of the trains, and the care that is taken in their erection renders them practically safe from doing anybody or anything the least harm even in the improbable event of their giving way. The storms of the present year have tried the systems most severely, and under this last one, which was of almost unprecedented violence, they have succumbed. But no positive blame attaches either to the Railway Companies or the Post Office authorities for what has happened. Probably no aerial system of telegraphs possible under the conditions necessary for the telegraphs of this country could have stood up against such a storm uninjured; and nobody would propose to put the existing aerial system underground, even if it were blown down more frequently than it is. Our sympathy is due to the owners of this property which has just been so unavoidably lost; and on the whole we think the railway companies are to be complimented for the promptness with which they adopted temporary expedients for signalling purposes that speedily enabled the trains to run with their accustomed punctuality. As regards the Post Office wires, the time has surely arrived for laying down supplementary lines underground to such of the great provincial towns as are not yet provided with them, and to the continental cables, which at present are rendered utterly useless through the breakage of a few land wires on our side of the Channel. A bitter complaint on this score reaches us from Germany, and will be found in another column. Still, in respect to the great bulk of the wires, their destruction can only be regarded as a national misfortune, which could not be avoided, and which we all deplore.

To the owners of aerial wires in the metropolis and suburbs we cannot, for obvious reasons, extend this sympathy, and we make haste to protest against the use that is being made of the disaster as a whole to cover the blame in respect to a particular portion of it. That the railway and roadway telegraph lines have been destroyed is no justification for the destruction of overhead wires in populous towns, nor is the actual immunity from personal injury in respect to both systems any excuse for the danger deliberately incurred by one of them. The wires that run by the side of the railways and along the highways are, we repeat, generally safe; those that run over our heads in the main thoroughfares of towns and cities are always unsafe. The latter are not so strong, and are not so carefully erected; the spans are often longer, and their poles often overtaxed; but more particularly they threaten passengers underneath, whereas the lines on the roads and railways imperil nobody. There is, therefore, no parallel between the two cases; and the only question remaining is whether the urban telegraph, or more correctly telephone, wires are of themselves perfectly secure. The answer to this question was partially answered by the storm of January last; and com-

Digitized by Google

pletely answered by the condition of London streets to day. Poles are still standing, and plenty of them; and there are numberless wires which to all appearance are in good condition; but look in whatever direction and locality we may, the rule is that both poles and wires have suffered disastrously. Quantities of broken wire hang down either sides of the streets, or are saved from falling only by being entangled in wires that have stood the brunt of the storm. In many instances the iron poles are bent into grotesque shapes, and the wires slacked into inextricable entanglement; while in not a few places complete breakage has happened, the poles overhanging the parapets with a mass of wire clinging to them, which any fresh gale of wind would precipitate headlong into the streets. The injury done to roofs and chimney stacks by falling poles and wires is not visible from the streets, but from more advantageous points of inspection we can certify that the devastation is as widespread as the most enthusiastic advocate of underground wires could desire. No one can say that the telephone companies, who are the chief sufferers, have not had plenty of warning, and no one can pity them for having paid no heed to it.

So very conspicuous are the effects of last Sunday's storm that the London newspaper press has given an unusual attention to the subject, with the result that the long delayed demand for putting these wires in safety underground is now being urged with greater vigour than ever. We trust that the Metropolitan Board of Works and the London vestries will not neglect to improve the occasion. It is our belief that much might be done by these authorities in the way of prohibition without any sanction of Parliament at all—much that the telephone companies would never dare to challenge in a court of law, for public opinion would be almost entirely on the side of restrictive interference. As a mere matter of police, the perilous condition of hundreds of wires which are now loosely festooning Fleet-street and the Strand might be peremptorily cured by cutting the wires adrift; and it would be the fault of the parishes if these wires are ever allowed to resume their former position. But we trust that no high-handed measures of this kind will be necessary. The shareholders of the companies by this time have surely had lessons enough in the expense of restoring communication to be satisfied that the safer system would be the cheaper. Not only have they to bear the cost of repairs and renewals, but the certain loss of custom. Renters will be chary of repeating their subscriptions to a system so easily put out of gear, and liable periodically to an utter break down for days and weeks at a stretch. Parliament, however, meets in about a month's time, and if directors of the Telephone Companies who disfigure and endanger the streets of London do not voluntarily reconsider their ways before then, we sincerely hope that powers to compel them will be sought for as soon as the Legislature assembles.

PRACTICAL DEDUCTIONS FROM THE FRANKLIN INSTITUTE TESTS OF DYNAMOS.*

BY CARL HERING.

The tests of dynamo-electric machines, made in 1885, under the auspices of the Franklin Institute are undoubtedly the most reliable and complete of all the impartial tests which have ever been made and published, and they therefore afford the practical electrical engineer an excellent opportunity to deduce proportions, dimensions and constants, to assist him in designing dynamos, especially as the machines which were tested are among the best that are made, and represent the results of tedious and expensive experimenting on the part of the makers, while at the same time they embody the improvements suggested by long and continued use of the machines in practice.

Dynamos have frequently been built by "guessing" at the proportions, constructing them, and then trying them to "see what they will give." If they then turn out (by chance) to give the electromotive force and current desired, the designer generally gets the credit for having made very correct "calculations;" while if they give, for some unknown reason, quite different results, the manufacturer has to be consoled with the statement that "it is not possible to calculate the parts of a dynamo."

If a machine is at hand which can be thoroughly tested and measured in all its parts, it is not difficult for a technical engineer who is well informed concerning the principles and practice of dynamo building to calculate the parts of another machine of the same type which will give a certain desired electromotive force and current slightly different from that of the first machine. But when the designer has no access to such a model machine, or if the current and potential desired differ greatly from those of the model, it is difficult, if not quite impossible, to calculate with any degree of certainty the parts of a dynamo from the principles and laws of induction and resistance without some practical constants and proportions, which can be obtained only from existing machines.

As an aid and guide in such calculations, a set of practical constants and proportions have been calculated by the writer from the valuable tests of the Franklin Institute. These constants will not only materially diminish the amount of "guessing" in designing machines, but it is believed they are sufficiently complete to enable a technical engineer to calculate all the electrical proportions of a well-designed cylindrical armature which is to give a certain required electromotive force and current. It is to be regretted that the data given in the Franklin Institute report are not sufficient to enable a similar complete set of constants to be deduced for the field. The calculations of armatures being based on induction and conductivity, the constants from one armature may be used in calculating others; but in the field this is not the case, as the relation between the exciting current and the magnetism produced depends very largely on the size, shape and proportions of the coils and the iron parts, including the cores, the so-called neutral parts, pole-pieces, &c, as well as on the quality of the iron. As these are so very different in different machines, the constants obtained from one would be of little use in determining the size of other fields, except perhaps, the constants given below for the intensity and amount of the magnetism of the field. A careful and systematic builder of dynamos will, in most cases, run the armature, when completed, with its own field-magnet frame with temporary, removable coils of known number of turns, on the magnets, in order to find, by regulating the current in these temporary field coils, how many ampere-turns are required in the field to induce the desired electromotive force and current in the armature. From this number of ampere-turns any competent dynamo builder can readily calculate the proper windings of the magnets with all due accuracy.

Numerous theories of dynamo-electric machines have been advanced, but most of them are of greater interest to the mathematician and the physicist than to the practical dynamo builder. More attention seems to have been given to integrals, complicated abstruse fractions and formulæ for determining the presumably correct values for extreme impossible cases, than to simple, practical formulæ, by means of which tangible results may be obtained for the ordinary forms of machines. In some cases, formulæ based on physical theories have been suggested, which might have been of practical use if accompanied by the absolute and reliable values of certain constants usually represented by Greek letters, which enter as direct factors in the formulæ; but the values of these constants have either been omitted, or else have been given within such wide ranges that they cannot be used to any advantage in practice. They are sometimes of such a nature that they differ for each machine, thus necessitating the construction and testing of the machine before the values of the constants for calculating this particular machine may be determined; which is, to say the least, a very awkward way of applying a formula.

The writer has, therefore, set aside all abstruse theories of the dynamo, which have yet to stand the severe test of varied practical application, and has endeavoured to deduce from the results given in the Franklin Institute report some constants, or values, which are in such a form that they may be directly applied to the calculations of the armature and some parts of the field. The deductions of these constants are based only on the well-known laws of induction and of mechanics, and as they are calculated from actual cases, they show what *is* done in practice, as distinguished from what *might be* done according to some theory, provided the theory is correct.

The results tabulated on the following page not only give the values which can be used in designing machines, but an attempt has also been made to determine the efficiency of separate parts, thus indicating under what circumstances the most advantageous proportions may be arrived at. Some proportions used in calculating the numbers given in the table were not contained in the report, and therefore had to be estimated, except where they were furnished to the writer by the kindness of the manufacturers. But the errors which may have been introduced by a slightly inaccurate estimate are so small that they do not materially affect the results. Certain slight errors, or modifications, in some of the figures or proportions were not taken into account, as they cannot be determined; but they are of such a nature as to affect equally, or approximately so, all machines not differing too widely from the style of those tested. Among these is the self-induction of the armature; in well-built machines, like those tested in which the field is intense, the speed not too high, the number of commutator bars or coils large, and the number of windings per coil very small, the self-induction will be very small, and, therefore, the difference between the self-induction in these different armatures may be neglected.

In the table given below, the deduced constants have been accompanied by many of the proportions from which they were derived, as copied from the report, in order to show some of the principal proportions of the machines, and to give the conditions under which the constants have the values given. Numerous other values in the report might have been repeated here, but as it is presumed that any one can obtain the original report, they are omitted. The values chosen for the deductions were taken from that one of the full load tests in which the current and potential were nearest to the values given by the makers as the best working load. (*See Table.*)

(To be continued.)

THE SELF-INDUCTION AND RESISTANCE OF COMPOUND CONDUCTORS.*

BY LORD RAYLEIGH, D.C.L.

Before entering upon the proper subject of this communication, I take the earliest opportunity of correcting a mistake of some importance into which I fell in connection with induction-coils. From the fact that a closed magnetic circuit acts very ill as a store of energy, I argued that closed electromagnets were to be condemned as secondary generators (*Phil. Mag.*, August, 1886, p. 179). Dr. Hopkinson and Prof. Ewing have independently drawn my attention to the fact that the success of induction coils does not depend upon storage of energy, and that they might work with high efficiency even though the whole of the energy put into the iron were wasted. Prof. Ewing's remark, to which I took exception, is thus perfectly correct.

I propose in the present paper to give an account of some investigations, mainly experimental, carried on during the summer months, which may, I hope, tend to settle some of the controverted questions which have been raised by the series of interesting experiments which were described in the spring of this year by Prof. Hughes.

Prof. Hughes's first apparatus consists of a Wheatstone quadrilateral, with a telephone in the bridge, one of the sides

* *Philosophical Magazine*, December, 1886.

Digitized by Google

of the quadrilateral being the wire or coil under examination, and the other three being the parts into which a single German-silver wire is divided by two sliding contacts. If the battery-branch be closed, and a suitable interrupter be introduced into the telephone-branch, balance may be obtained by shifting the contacts. *Provided that the interrupter introduces no electromotive force of its own*,* the balance indicates the proportionality of the four resistances. If P be the unknown resistance of the conductor under test Q, R the resistances of the adjacent parts of the divided wire, S that of the opposite part (between the sliding contacts), then, by the ordinary rule, $PS = QR$; while Q, R, S are subject to the relation

$$Q + R + S = W,$$

W being a constant. If now the interrupter be transferred from the telephone to the battery-branch, the balance is usually disturbed on account of induction, and cannot be restored by any mere shifting of the contacts. In order to compensate the induction, another influence of the same kind must be introduced. It is here that the peculiarity of the apparatus lies. A coil is inserted in the battery and another in the telephone branch, which act inductively upon one another, and are so mounted that the effect may be readily varied. The two coils may be concentric and relatively movable about the common diameter. In this case the action vanishes when the planes are perpendicular. If one coil be very much smaller than the other, the coefficient of mutual induction M is proportional to the cosine of the angle between the planes. By means of the *two* adjustments, the sliding contact and the rotating coil, it is usually possible to obtain a fair silence.

In his address Prof. Hughes interpreted his observations on the basis of an assumption that the self-induction of P was represented by M irrespective of resistance, and that the resistance to variable currents could (as in the case of steady currents) be equated to QR/S. In the discussion which followed I pointed out that this was by no means generally true, and I gave the following formulæ† as applicable to the case in which the only sensible induction among the sides of the quadrilateral is the self-induction L of the conductor P :—

$$QR - SP = p^2 ML, \quad . \quad . \quad . \quad (1)$$

$$M(P + Q + R + S) = SL. \quad . \quad . \quad . \quad . \quad (2)$$

The electrical vibrations are here supposed to follow the harmonic law, with frequency $p/2\pi$. "It will be seen that the ordinary resistance balance ($SP = QR$) is departed from. The change here considered is peculiar to the apparatus, and, so far as its influence is concerned, it does not indicate a real alteration of resistance in the wire. Moreover, since p is involved, the disturbance depends upon the rapidity of vibration, so that in the case of ordinary mixed sounds silence can be attained only approximately. Again, from the second equation we see that M is not in general a correct measure of the value of L. If, however, P be very small, the desired condition of things is approached; since, by the construction of the apparatus, $Q + R + S$ is constant (say W), and if P be small enough S does not differ much from W, *i.e.*, most of the wire forming the three sides of the combination is devoted to the member opposite P."

The formulæ are easily proved. Since there is no current through the bridge, there must be the same current (x) in P and one of the adjacent sides (say) R, and for a like reason the same current y in the sides Q and S. The difference of potentials at time t between the junction of P and R and the junction of Q and S may be expressed by each of the three following equated quantities :—

$$Qy - Px - L\frac{dx}{dt} = -M\frac{d(x+y)}{dt} = Rx - Sy;$$

from which the required results are obtained by elimination of the ratio $x : y$, and introduction of the supposition that all the quantities very harmonically with frequency $p/2\pi$.

The inadequacy of Prof. Hughes's original interpretation has been remarked upon also by Prof. Weber‡ and by Mr. O. Heaviside,§ who have obtained the corrected formulæ. I give them here because I agree with Prof. Weber that this form of apparatus possesses distinct advantages. As he points out, if P be known, the application of (2) really presents no difficulty, and allows of L being readily found in terms of M.

There are many cases in which we may be sure beforehand that P (the effective resistance of the conductor, or combination of conductors, to the variable currents) is the same as if the currents were steady, and then P may be regarded as known. There are other cases, however—some of them will be treated below—in which this assumption cannot be made; and it is impossible to determine the unknown quantities L and P from (2) alone. We may now fall back upon (1). By means of the two equations, P and L can always be found in terms of the other quantities. But among these is included the frequency of vibration; so that the method is only practically applicable when the interrupter is such as to give an absolute periodicity. A scraping contact, otherwise very convenient, is thus excluded*; and this is undoubtedly an objection to the method.

My own experiments have been made with three different forms of apparatus. The first was constructed upon the model of that originally described by Hughes, and still to be preferred for some purposes. The others will be described in due course; but it will be convenient to consider first those parts which are common—the interrupters and the induction-compensators.

A thoroughly satisfactory interrupter with a definite period has not, to my knowledge, been constructed. Tuning-forks, driven electro-magnetically with liquid or solid contacts, answer well so long as the frequency required does not exceed 128 or 256 per second; but here we desire frequencies of from 500 to 2,000. My experiments have been made with harmonium-reeds as interrupters, the vibrating tongue making contact once during each period with the slightly rounded end of a brass or iron wire, which can be advanced exactly to the required position by means of a screw cut upon it. Blown with a well regulated wind, such reeds have given good results even up to 2,000 (complete) vibrations per second; but they are often capricious and demand frequent readjustment. The reed which I have usually employed makes about 1,050 vibrations per second, and answered its purpose fairly well.

The induction compensator is similar to that used by Prof. Hughes, and consists of a small coil mounted so that one diameter coincides with a diameter of a larger coil, and movable about that diameter. The mutual induction M between the two circuits depends upon the position given to the smaller coil, which is read off by a pointer attached to it, and moving over a graduated circle. The circles are so divided that the reading (θ) would† be zero when the *axes* of the coils were coincident, or the planes parallel. In this position M is arithmetically a maximum (M_0); and we consider its algebraic sign to be positive. At 90°, when the axes are at right angles, $M = 0$. At 180° M would be negative, and of the same arithmetic value (M_0) as at 0°.

The coils are wound upon boxwood rings, and in each there are 45 convolutions. The mean diameters are about 3in. and 1½in.

Lord Rayleigh next described the method by which the calibration of the compensators was performed. He then proceeds :—These results led to the unexpected conclusion that from 40° to 140°, *i.e.*, through a range of 100° about the perpendicular position, the scale of induction does not differ appreciably from the scale of degrees. From 30° to 40°, or from 140° to 150°, the induction is something like a tenth part less than that corresponding to 10° in the neighbourhood of 90°. Within the whole mechanical range of the instruments, from 30° to 150°, there could scarcely be an error of 2 per cent. in assuming M proportional to the angle measured from perpendicularity, *i.e.* $(\frac{1}{2}\pi - \theta)$, or, say, θ'.

The general explanation of this very convenient property is not difficult to understand; since for high values of θ' the approximation over the whole circumference of coils of not very unequal diameters must lead to a more rapid increase of

* This condition is not always satisfied. With the reed-interrupter (see below) a loud sound may sometimes be heard, although the battery-branch be open. † *Jour.* Tel. Eng., Vol. XV., p. 54.

Digitized by Google

M than if the smaller coil were very small; and it is conceivable that for some particular ratio of diameters the increase may just so much exceed that represented by sin θ', as to correspond nearly to θ'.

The absolute value of the induction-coefficient corresponding to each degree of the compensators was determined at the time of the calibration by comparison with the calculable induction-coefficient between two coils wound in measured grooves cut on the surface of a wooden cylinder.

By this means it was shown that every degree of either compensator, not too far removed from the middle of the range, represents 776·3 centim. of induction-coefficient.

The maximum coefficient, when $\theta = 0$, would be about 56,100 centim.

(To be continued.)

THE NEWCASTLE EXHIBITION.

The contracts for the electric lighting of this Exhibition have been awarded as follows:—Messrs. Clark, Chapman, Parsons and Co., for lighting the whole of the courts of the building, and to supply engines and boilers; Messrs. J. H. Holmes and Co., for lighting the Art Gallery; and Messrs. Paris and Scott, for lighting a portion of the inner garden. The tenders were sent in on the basis of the following specification:—

Conditions under which the Executive Committee are prepared to receive Tenders for Electric Lighting.—The Executive will provide engine-power, counter shaft, and driving drum; also foundations and holding-down bolts for the dynamos; and shall be responsible for providing the stipulated brake horse-power on the counter shaft, and linear velocity of periphery of driving drum. Contractors are to provide driving belts from counter shaft to dynamos, and to be responsible for the efficient working of all parts from the counter shaft to the lights.

Persons tendering are to specify the brake horse-power required on the counter shaft, and the linear speed of belt. If their tender is accepted, they are forthwith to send to the engineer of the Exhibition a templet, corresponding to the base plate of the dynamo or dynamos proposed to be employed, to enable the executive to prepare the necessary foundations.

In cases where the engine is on one foundation with the dynamo, or for any other reason the persons tendering wish to provide their own engines, the tender is to specify the nature and approximate dimensions of the engine employed, the steam pressure in lbs. per square inch above atmospheric pressure, the number of lbs. of steam per hour required, and the dimensions of the steam pipe. The executive will then be responsible for the supply of steam, but the contractors must be responsible for the efficiency of all parts beyond the steam connection provided. The foundations of the engines will be provided by the executive, according to specification to be supplied by the contractor.

Contractors are to supply all driving belts, dynamos, leads, switches, cut-outs, lamps and fittings, carbons, and all other requisites, with all fixing and labour; and to be responsible for the efficient carrying out of the work.

Each contractor shall apply one volt meter and one current meter, suitable for each type of installation for which he is responsible.

Every arc lamp outside the building shall be provided with a suitable reflector, placed above it, and not less than 2ft. 6in. in diameter; and every 50-candle incandescent lamp shall be provided with an opal glass reflector, not less than 7in. in diameter.

No leads shall be carried on the outside of the building, nor shall the contractors or their *employés* have access to the outside of the roof, on any pretext whatever. Every facility shall be given to contractors to carry their leads anywhere within the building, consistent with the safety of the public and the availability of the space for exhibits, provided that cables shall not be carried in open spans where, in the opinion of the executive or their superintendent, such spans are a disfigurement to the building.

All work shall be done by the contractors to the satisfaction of the agents of the several insurance companies interested in the building and contents, and safety cut-outs shall be inserted in the leads wherever required by such insurance agents.

If it is proposed to employ continuous currents of a higher E.M.F. than 400 volts, or alternating currents of higher E.M.F. than 200 volts, the tender shall be accompanied with a detailed specification of the precautions which it is intended shall be taken to provide against fire risks, and for the safety of the public and of the attendants.

The accompanying plan shows the number and character of the lights which it is proposed to place in the several sections; but the executive reserve the right to alter the position of any lamp or lamps, provided that such alteration does not necessitate an increased amount of lead.

As it will not be possible in all cases to give to persons tendering the particular section selected by them, it is desirable that each tender, while specifying the section preferred, should quote for more than one section.

Any person tendering may substitute incandescent lamps, in groups, or otherwise distributed (the mode of distribution to be described in the tender), for any arc lamps marked on the plan, according to the following scale:—For every 350 watt lamp, incandescent lamps of 500 nominal candle-power; for every 500 watt lamp, incandescent lamps of 800 nominal candle-power; for every 750 watt lamp, incandescent lamps of 1,200 nominal candle-power, and such tenders will receive the same consideration as those based on the distribution of lamps shown in the plan.

Any person may tender for one or more, or for *all* the nine sections mentioned below, but each tender must specify the sum to be charged according as one or more sections are allotted.

Each tender to state what additional sum per lamp is to be added if the number of lamps is increased by any number not exceeding 30 per cent. of the number specified, and the executive reserve the right of increasing the number of lamps in each section by any amount up to 30 per cent. of the original number on the basis of such tender.

The installation shall be completed by the 9th of April, from which date the penalties defined in Clause 24 shall be enforced. After the 9th day of April, and until one week previous to the opening of the Exhibition, the contractor shall light such lamps as may be ordered by the superintendent, at any hour between six a.m. and midnight, during the week preceding the opening at any hour whatever, and from the opening day till the Exhibition closes at any time while the Exhibition is open, and until all visitors shall have left.

The tenders shall be based on the assumption of 500 hours' lighting between April 9 and October 31; but a separate clause shall be added stating the amount to be charged per hour for every hour beyond 500 between these dates, and a further clause stating the amount to be charged for every hour after October 31, on the understanding that if the Exhibition is kept open after October 31 the lights will be required for at least six hours per day.

The superintendent of the Exhibition shall give each day to the contractor or his representative a written order, stating the hours during which the lights are to be running, and these orders shall be accepted as the basis on which the number of hours of lighting shall be calculated.

Payments shall be made monthly to the extent of 75 per cent. of the amount due, and the remainder shall be paid in full within one month after the closing of the Exhibition.

The contractor shall, when requested by the superintendent with the authority of the executive, remove from the work permanently any foreman, workman, or attendant who may be considered by the executive to be incompent or insubordinate, and the contractor shall forthwith substitute other foreman, workman, or attendant in his stead.

The contractor shall be liable for any damage to any part of the buildings, or exhibits, or accessories thereto, or to any person or animal, and shall be liable for any damage whatever, whether by trespass or otherwise.

No extras shall be allowed, or paid for, unless the contractor can produce an official order for the same, signed by the superintendent of the Exhibition, and describing each particular item.

Each tender shall contain a description of all lamps proposed to be employed, stating the E.M.F. and current required by each, and the contractor shall be responsible for providing the full current to each lamp. If the current or E.M.F. supplied is allowed to fall short by more than 5 per cent. of the number of amperes or volts specified the lamps shall be deemed to be unlighted, and the contractor shall become liable for the penalty defined in Clause 24.

The executive shall be responsible for providing the power stipulated in the contract. If the contractor require more power than that agreed upon for the number of lamps the contractor shall pay to the executive the sum of 3d. per hour for each brake horse-power so required at the counter-shafts, and the executive shall have power to deduct such charge from the monthly payments to the contractor.

For every lamp not alight when required, a penalty may be inflicted according to the following scale, and the amount of such penalties shall be deducted from time to time from the monthly sums payable to such contractor:—(*a*) For a single arc lamp, for every half-hour or portion of half-an-hour, the sum of one shilling. (*b*) If more than one arc lamp in the same section is extinct at such time as it should be alight the penalty shall be reckoned as for a single lamp, but shall be proportional to the square of the number of lamps extinct at the same time. Thus for two lamps extinct it shall be 4s. for every half-hour or portion of half an hour, for three lamps 9s., and so on. (c) For every incandescent lamp extinct for more than one evening the penalty shall be 1s. per evening for a

Digitized by Google

nominal 20-candle lamp, 2s. for every 50-candle lamp. When more than fourteen 20 candle-power lamps or five 50 candle-power lamps are extinct in the same section, the penalty shall be calculated as for arc lamps, every group of 300 candle-power being reckoned as equivalent to one arc lamp. Single incandescent lamps of 300 candle-power or upwards shall be regarded for the purposes of this clause as equivalent to arc lamps, unless extinct through the breaking of a filament and replaced within reasonable time.

If the penalty inflicted under the last clause amount during any week to more than £40, or the contractor become bankrupt, the executive shall have the right to annul the contract, and to cause the plant belonging to such defaulting contractor to be removed, but shall retain a lien upon such plant to the extent of any penalties and expenses which may be incurred through the default. Penalties and expenses may be deducted from any money due under the contract, or may be recovered from the contractor as and for liquidated and ascertained damages.

Any question relating to the interpretation of these conditions shall be referred to the chairman of the Lighting Committee, whose decision shall be final. The sections for which tenders are now invited are the following:—(A) For 32 arc lamps, each absorbing 350 watts, for the central span of the north court. (B) For 36 arc lamps, each absorbing 500 watts, and one arc lamp absorbing 750 watts, in the entrance hall and side spans of the north court. (C) For 35 arc lamps, each absorbing 500 watts in the east, south, and west courts. (D) For 8 arc lamps in engine shed, 8 in dining room, 8 in concert room, 12 in central garden, carried on 4 masts, each 35ft. in height, in all 36 arc lamps, each absorbing 500 watts (and four masts). (E) For 100 incandescent lamps in verandah, 60 incandescent lamps around band stand, 120 incandescent lamps on and above the entrance porch outside the building, and 40 incandescent lamps in the offices at the entrance, in all 320 incandescent lamps of 20 candlepower, and one group of incandescent lamps in the band stand of 300 candle-power in the aggregate. (F) For 114 incandescent lamps of 50 candle-power in the annexe adjoining the verandah, and four groups of lamps, of not less than 300 candle-power each in the corner refreshment rooms. (G) For 127 incandescent lamps, of 50 candle-power each, in the annexe surrounding the building. (H) For 400 incandescent lamps, of 20 candle-power, in the art gallery. In this gallery special supports for the lamps will be provided by the executive, but the usual holders and the wiring must be provided by the contractor. (K) For 55 incandescent lamps, of 20 candle-power, in the coal mine. The mine will be about 150 yards in length, and proceed northwards from the middle of the north end of the Exhibition.

The plans of the engine room, dining rooms, concert room, and art gallery are not yet complete. The art gallery will consist of two spans, each of 30ft. in width, and about 140ft. in length. The lamps will be placed at intervals of about 18in. on a frame provided by the executive, and furnished with suitable supports for the lamp holders.

NOTE.—By the term 20-candle lamp is to be understood what is now generally called a 16-candle lamp. A number of additional lamps will be required for the grounds (which will comprise about 14 acres) and various detached buildings placed therein, but these will form the subject of future contracts.

SOME EXPERIMENTS ON SECONDARY CELLS.

BY JAMES SWINBURNE.

(Continued from page 154.)

Carbon for Peroxide Plates.—The practice of making peroxide plates of carbon does not seem to be quite abandoned even yet. Carbon is more easily oxidised than is popularly supposed; in fact, Brodie's process for disintegrating graphite depends on the action of an oxidising agent. We tried some Faure plates with carbon in dilute sulphuric acid and in a solution of zinc sulphate. In both cases the carbon was attacked. After standing for some days the peroxide plates seemed quite good, and the peroxide appeared to stick well to the carbon and to form good coatings. On examination, however, it was found that the carbon under the peroxide was converted into a soft black pulp. Carbon was tried as anode in various solutions, such as sodium carbonate, sodium phosphate, phosphoric acid, dilute sulphuric acid, potassium fluoride, potassium sulphide, hydrochloric acid, liver of potassium, potassium chromate, ferri-cyanide, ferro-cyanide, permanganate, borax, potassium tungstate, potassium hydrate, sodium chloride, &c. In all cases where oxygen would otherwise have to be evolved the carbon was attacked, but when a current could pass by evolving chlorine the carbon was not attacked. As peroxide of lead acts on a chloride in an acid solution, carbon is evidently useless for peroxide plates. It may do admirably for bleaching or evolving chlorine or making hypochlorites. The same conclusions were arrived at by Bartoli. Biscuit, or unglazed porcelain, impregnated with carbon deposited from hydrocarbon by heat, was tried. It split into small pieces. It is odd that none of the sufferers from primary battery disease have used this material for porous pots, as many of them have the idea that a carbon porous pot somehow reduces the resistance of the cell.

As no metals were available as indestructible supports for the oxidised plate in dilute sulphuric acid, and as carbon also appeared useless, the next thing was to try to make the supports of peroxide itself. Peroxide made by oxidising coatings made originally from litharge or red lead was not hard enough to make good supports; but the peroxide deposited by electrolysis of an alkaline solution of a lead salt was very much harder. The best way seemed to be to make a paste of litharge and caustic soda, and to attach it to the lead plate and make it the anode in a solution of caustic soda. When the whole of the litharge was oxidised the lead plate was removed. The resulting peroxide was very hard, and seemed quite impervious; when a bit was used as a plate in a cell, and the cell discharged, it ran down at once, the peroxide being covered by a very thin film of lead sulphate. The surface seemed to be the only part in contact with the acid. It would be a matter of great practical difficulty to make cells with peroxide supports commercially. It would be interesting to know how this form of peroxide compares with Mr. FitzGerald's *lithanode* in point of hardness and durability. The peroxide from a solution of nitrate and tartrate of lead looks very dense and hard, but it comes in the form of scales resembling iodine. Before leaving the subject of lead plates some experiments on lead sulphate must be described. It was supposed at one time that lead sulphate could not be reduced in dilute acid. Sir William Thomson had made experiments with it, and had found it would not reduce. We made a cell with platinum plates and precipitated lead sulphate in dilute sulphuric acid; it was charged for five weeks, and at the end of that time the sulphate on one was completely oxidised, but on the other it was only reduced here and there in spots. A similar cell was then started with a little litharge mixed with the sulphate; the sulphate then reduced perfectly. This is a result of some importance. The reduction of sulphate seems to be purely a question of good contact. In many cells which gave very small outputs the reduced plates were found to be in fault. The slightest film of thoroughly-formed sulphate acts as a perfect insulator. It is a good plan to keep a small cell always ready with both plates fully charged; then, when a cell under test runs down, each plate is separately tried with a proof plate, and it is then found which of the plates has failed. The film of sulphate formed on a piece of lead reduces all right, but as sulphate of lead is very bulky its formation seems to cause buckling about and resulting bad contacts. To see how great the swelling due to the formation of sulphate of lead is, the specific gravities were taken, and the following are the resulting figures:—

100 volumes of lead form—

Peroxide of lead	160
Red lead	143
Litharge	151
Lead sulphate	297

This shows that lead converted into sulphate swells into three times its original bulk, and that peroxide on becoming sulphate is doubled in volume; this at once shows why coatings tumble off plates. To see how much of the active material in a cell is really used, several plates were made up with weighed quantities of lead oxides. One of these was a little Sellon plate, made of a piece of a large plate filled with minium or litharge; others were Faure plates. After charging, the plates were short-circuited through copper voltameters. The maximum output was from 5 to 7 per cent. of that calculated.

Many attempts were made to make coatings that would stick well. Collodion was of no use; litharge and sugar did not make good coating; sodium silicate mixed with the litharge before applying was useless. Litharge and glycerine form a very useful cement known as engineers' cement. Though the coating was very easy to manage, there seemed to be no permanent advantage in using glycerine. This coating has been patented. In those days it was usual to wrap plates in flannel to keep the coating on. The flannel generally went to pieces very soon; it appeared, however, that this is not due to the action of the acid, but to oxidation through contact with the peroxide. Asbestos paper is too weak to be of any use. Cotton or linen is soon destroyed by acid, but resist strong alkali longer; while flannel resists acid, but is attacked by alkali. Pyroxylin is easily attacked by alkali, not easily by acid. Tribe proposed to use pyroxylin for supporting plates. Xylonite has also been tried for me more recently by Mr. Cathcart, then my assistant. It is much the same as celluloid, being made of pyroxylin and nitrobenzole, camphor, or some such solvent. This will stand being boiled in moderately strong sulphuric acid for a long time, and should be very useful in battery work. Flannel was soaked in collodion, with the idea that the fibres might thus be protected, but they were not. Flannel was also soaked in sodium silicate and attacked with sulphuric acid; it succumbed.

Strength of Acid.—It was usual to use acid of a strength of 1 to 10. This probably arises from that being the strength in vogue for Daniell batteries.

The strength of acid was also not considered, because the action of secondary batteries was for some unaccountable reason supposed to be due to the formation of litharge on both plates. I am afraid Dr. Lodge was much to blame for perpetuating this error. Another absurd theory was that the action is due to occluded hydrogen in the reduced plate. It has been said that the study of secondary batteries belongs to chemists, not to electricians; but it is strange that when chemists have to deal with electrolysis they seem to forget their chemistry, or to imagine that the laws of chemistry no longer hold good. As the action of the cell depends on the formation of lead sulphate, it is clearly an advantage to have as much acid as possible available in the coatings.

On looking into Gladstone and Tribe's book on secondary batteries they are found to state that the action on the peroxide plate is as follows:—The peroxide is reduced to monoxide, and the sulphuric acid then combines with this to form lead sulphate and water. If this were the case the energy due to the combination of the lead with the sulphion would be entirely converted into heat, not into electrical energy. Chemists have a lot of time-honoured ideas which do not at all fit the facts of electrolysis. One is that salts are formed by the combination of an acid and an alkali.

Digitized by Google

In old days people spoke of the sulphate of the protoxide of lead and so forth, and lead sulphate was represented as PbO,SO_3 when it was understood that the water was eliminated. Even now chemists seem to assume, without foundation, that a metal cannot form a salt without passing through the intermediate state of oxide, though really an oxide is itself just as much a salt as a nitrate or sulphate. If electrolysis proves anything at all it is that a salt is made up of an electro-negative and an electro-positive radicle, not of a base and an acid with some water eliminated. The action of an acid and an alkali is simply the exchange of radicles, the most electro-negative radicle combining with the most electro-positive, making a salt in which neither preponderates, or, as it is called, a neutral salt.

If the coatings have only weak acid, it may be all absorbed when the cell is discharged a little, and the electromotive force will fall, and there will be a tendency to the formation of basic salts in the coatings; but, on the other hand, if the acid is made stronger, it may be decomposed without electrolysis, as when peroxide of lead evolves oxygen and forms lead sulphate, or as when spongy lead evolves hydrogen and forms lead sulphate. In the case of spongy lead there may or may not be electrolysis. If the acid is so strong that the lead decomposes it directly, there is no local action; but if there be some more electro-negative metal, such as, say, antimony, in contact with it to evolve the hydrogen, there is electrolysis.

Another universally accepted theory without any foundation is that all electrolysis is due to the action of nascent hydrogen or oxygen. In old times when someone saw bubbles coming off zinc in an acid solution of, say, an iron persalt, and found the persalt was reduced to a protosalt, he naturally supposed the gas was the cause of the action. But there is no reason to suppose the hydrogen has anything to do with it. It takes a certain electromotive force to give off the hydrogen, and a certain less electromotive force to reduce the persalt. If the available electromotive force is between these values, the persalt will be reduced without any hydrogen being formed. To suppose that hydrogen is first formed, and that the thing then changes its mind and does an easier chemical action, is unphilosophical. The combination of the zinc with the available negative radicle will go on, the action being made possible by the reduction of the persalt when present, and by evolution of gas when no persalt is present at that spot. The nascent gas idea is like saying that when one goes up to the first floor one goes to the roof and tumbles down again to the first floor.

Still further reduction takes place in thousands of ordinary chemical actions where no hydrogen is present, as when carbon monoxide is passed over hot litharge. Again, electrolysis takes place quite well without hydrogen or oxygen being present, as when a fused metallic chloride is electrolysed.

Another unfounded theory is that it is the water that does all the conducting, and that it is first decomposed, the other action being secondary. Pure water does not conduct, neither does pure sulphuric acid, but the mixture does; how, then, is it inferred that the water only of the mixture conducts? No doubt the only way to study electrolysis is to divest it of all pre-conceived theories that have no logical foundations, and to study thermo-chemistry.

The best strength of acid was not determined by us, and it no doubt depends on the purity of the lead, and of all the compounds forming the coatings, and of the acid itself. It also depends on the way the cells are to be used. If the acid is strong, both oxygen and hydrogen will be given off slowly, even during several weeks. As the idea of using secondary batteries as magazines for storing energy for long periods is being given up, this slow decomposition is of little importance; but there is another point—that is, that sulphuric acid which is not very dilute separates into two strata of different specific gravities. Before leaving the subject of lead cells it may be as well to mention that the troublesome spray that comes during charging may be prevented by floating paraffin on the top of the acid. The spray not only tarnishes, rusts, or destroys everything near, but is the cause of all sorts of ground leaks. The paraffin prevents the acid from creeping; in fact, it creeps itself, and acts as an insulator.

Alkaline Cells.—It is well known that iron is very electro-negative in an alkaline solution; but such solutions as that of caustic soda or potash are not available, because nearly all salts of lead are soluble in them. It was therefore attempted to make cells with iron supports in an alkaline solution of some salt whose acid radicle would not attack iron, and would precipitate lead salts. Iron in solutions of potassium cyanide, ferrocyanide, and ferri-cyanide was attacked; the ferro-cyanide or yellow prussiate of potash plate was least eaten. Even such salts as sodium sulphate dissolve some lead sulphate. This property is important in connection with ordinary secondary batteries. A little sodium sulphate mixed with the acid may tend to make the sulphate of lead more easily reduced; as, when all the sulphate is reduced that is in contact with the support, hydrogen is evolved, and caustic soda is formed in the immediate neighbourhood of the plate, and can dissolve the sulphate, the lead being then precipitated as spongy lead. The spongy lead can thus make contact with the sulphate. Magnesium sulphate has been recommended as a solution, but it is difficult to see why. Zinc sulphate might be good. Alkaline sulphides of course attack iron.

Iron plates with coatings of white lead in solutions of sodium carbonate: these oxidised and reduced very well, but the iron seemed to be slightly attacked. On testing the peroxide traces of iron were found. Thinking the corrosion of the plate was perhaps due to impurities in the carbonate, such as sulphate, experiments were tried with the purified salts. The iron seemed to be in a sort of unstable state. Sometimes it would remain quite clear and bright in contact with the peroxide, and with bubbles of oxygen evolving from its surface; but suddenly a green spot would appear, due, no doubt, to the formation of carbonate of iron, and this spot would extend and cover the whole plate. The best results were got with bicarbonate of soda.

Nickel was tried in the same solutions. It behaved in the same way, though it was not quite so easily attacked. The carbonate was lighter in colour, being apple green. Iron plates with borax solution: green discoloration. Iron plate with caustic, potash, and tannin: iron eaten. Some cells were tried with iron plates and ammonia; but as it is probable that nitric acid would soon be formed in them they were abandoned. The alkaline cells gave 1·7 volt. The measurements were taken roughly. A calibrated tangent galvanometer was used as a voltmeter; for measuring currents a low resistance was made up consisting of a lot of wires put in parallel, their resistance having been measured in series. Ammonia sometimes gave a brown deposit with iron plates.

As it seemed hopeless to get iron to stand without being attacked, various methods of protecting it were tried. Iron gauze was coated with peroxide by making it the anode in a solution of litharge in caustic. When this solution is electrolysed clouds of litharge are evolved close to the plate. This is very curious, for if the solution is plumbite of lead the electro-negative radicle would be PbO_2, not PbO; such a salt being presumably $Na_2 PbO_2$. It is very probable that this deposit was not due to electrolysis; but to the solution becoming more alkaline at one side than the other, thus depositing the litharge. Peroxide of lead deposited from solution of lithage in caustic is too dense to be used as an active coating; it was proposed to use it to protect the iron, and to have then applied a coat of porous peroxide such as is used in acid cells. The peroxide was never satisfactory. To make up for the imperviousness of the peroxide, red lead and water were rubbed into the pile of velvet; the velvet was placed with its face against the iron plate, and the coating was oxidised in an alkaline solution. The velvet was then dissolved out by strong alkali, so as to leave a coating with a very large surface. The plate, however, had very small capacity. Electro-gilding the iron was then resorted to. It is a little difficult to gild iron, as the gold does not stick well. After each coat of gold the iron was heated to make the gold sink in. The gilded plates did not answer well. The Bower-Barff process for protecting iron from rust was tried, by getting an ornamental railing top and making it the anode in a cell. The black oxide did not prove to be a good enough protection. The strange thing about the corrosion of iron in alkaline solutions is that it does not take place if there is no coating. A piece of sheet iron may be used as anode in the solution of carbonate or bicarbonate of soda without being the least corroded; but if a coating of, say, white lead is applied, green spots appear at once, but only under the white lead; the back of the plate remains quite clear. Oddly enough, sheet tin is not easily attacked by an alkaline solution. Sometimes it turns black, or the surface, which consists of an alloy composed chiefly of tin, peels off in black scales. Sheet tin behaved much as iron or nickel; that is to say, it behaved very well till a coating was put on, and then it was corroded. There is a very curious alloy of iron and tin. If iron and tin are melted together, the resulting alloy separates into two portions; one is approximately Fe Sn, and the other consists chiefly of tin, and has a low melting point. The alloy Fe Sn solidifies at a red heat. It was too unmanageable to be of much use for batteries, and it was no better than sheet tin; but it was so hard that a straw-hardened cold chisel even would not cut it, but broke in pieces, while a softer chisel turned up at the edge. This alloy might be useful in commerce. The writer has since tried to make more of this alloy for some experiments on persistent magnetism, but has never succeeded in making it so hard again.

Iron without a coating is not attacked in such solutions as potassium bichromate, or permanganate. At first sight this seems strange, but it must be remembered that such salts owe their corrosive properties, especially when acting on organic bodies, not to the strength of their acid radicles, but to the electro-positiveness of chromium and manganese, which makes them combine energetically with an acid radicle to form chromium or manganese salts. Thus potassium bichromate or chromic acid in the presence of sulphuric acid is a very powerful oxidising agent, but if there is no acid present to form a chromium salt it is no longer energetic. Iron in alkaline solutions is very convenient for adjustable water resistances.

We worked at iron cells with some tenacity, because we seemed to be very near success; and if we could make a peroxide plate with iron without local action, the negative might be of zinc, as this combination gives a high electromotive force.

Cells with Zinc.—Evidently cells with zinc could not be used in most acid solutions, as so many of its salts are soluble. Secondary batteries with zinc plates have often been brought out; but as the zinc dissolved on discharging is not deposited on the same part of the plate on charging, these cells cannot well be used very often. M. Reyneir has lately worked at cells with zinc in sulphuric acid and Planté peroxide plates. He does not say how he proposes to get over the difficulty of the zinc being deposited in the wrong place. He says that the deposited zinc is so pure that there is very little local action. His cells give 2·37 volts.

We tried plates with reduced zinc coatings in alkaline solutions that do not dissolve zinc, such as sodium carbonate and sodium bicarbonate. The coatings were made of oxide or carbonate of zinc. The chief trouble was the proper reduction of the zinc. These salts of zinc behave very much like lead sulphate—that is to say, they are very bulky—and the coatings form hard white cakes which are not in good contact with the support. When the zinc is eventually reduced it is very soft and loose. Very likely we made a mistake in reducing coatings of oxide or carbonate of zinc, instead of forming the coating out of the solid plate by attacking it when used as anode. The object aimed at was the use of iron for the support of lead peroxide in the other element; but as we did not get iron to work satisfactorily, we did not do very much with the zinc.

Primary Cells.—A few experiments were made, but they are not worth recording. Lately, however, the writer saw a note in *The Electrician* to

Digitized by Google

the effect that a French *savant* had used agar-agar jelly in a Leclanché cell. It seemed possible that the use of this might avoid the necessity for a porous pot in a two-fluid cell, the idea being that to make up a cell one might take a zinc plate, place on it a wad of zinc sulphate jelly, place on that a wad of copper sulphate jelly, and cover it with a copper plate. Zinc and copper jellies are easily made, but the drawback is the rapid diffusion of the copper salt. Some cells were made with zinc filings suspended in the zinc jelly, so that any wandering copper salt might be caught before it reached the zinc plate. As rapid diffusion is always the result of a low-resistance porous cell, it seems useless to try to make a low-resistance two-fluid cell unless some colloïd oxidising agent can be found. Some of the solutions of iron were found by Graham to be colloïdal ; perhaps something might be done with them.

A bichromate jelly cell was tried, but it was also a failure. The same thing was noticed as in the case of flannel and cotton. Bichromate jelly with no acid keeps for any length of time ; and sulphuric acid jelly can also be made ; but the jelly dissolves at once if both acid and bichromate are present. The same things happens with potassium permanganate.

Agar-agar is a fucus or seaweed. It has, if the writer is not mistaken, the same composition as starch. It has a very high gelatinising power—about ten times that of gelatine. It is probably used for sizing paper or calico, or for cooking. Mr. Stanford, of Glasgow, is an authority on the uses of seaweeds.

Gelatine was tried, but it was liable to go bad, and was at once attacked by oxidising agents.

Probably gelatinous silica may do, but the writer has not yet made enough experiments to say. A low-resistance bichromate cell in which the bichromate had not access to the zinc would be very useful where a large power is occasionally required, as in the laboratory.

Miscellaneous.—While various cells were being charged or discharged there were often odd quarters of hours to spare. These were spent in trying different experiments not connected directly with secondary cells.

White Lead.—It was attempted to make white lead electrolytically. The present method of making white lead, which is felicitously termed the "Dutch process," is slow and barbarous, and exceedingly unhealthy. The women who are continually among the white lead absorb the lead through their skins, or perhaps swallow it little by little, and are apt to suffer from lead poisoning. Messrs. Cookson and Co. have probably the best sanitary regulations and arrangements in the world ; but even then the Dutch process is very dangerous.

To make white lead electrolytically, plates of lead were made anodes in solutions of carbonate or bicarbonate of soda, with very small currents In many cases white deposits were obtained, but in no case was any quantity obtained. If the current was increased the plate was soon coated with a brown compound. To imitate the action of the basic acetate a little acetic acid was added to some of the solutions. In some cases a very curious phenomenon was seen. Long white columns like small candle drippings started about the middle of the plate, and grew down to the bottom of the beaker. The plates were about three inches from the bottom.

Experiments were tried with lead plates and solutions of salt with a view of making white oxychloride of lead. The plates were, of course, easily attacked, but if the current was very small the coating formed very slowly, and appeared crystalline, and if the current was increased the coating turned brown.

Sodium Chlorate.—Potassium chlorate is very largely used for making English matches, and in dyeing. It is probably used instead of sodium chlorate because it can easily be separated from chloride by crystallisation. To make sodium chlorate, solution of salt was electrolysed. This gives off chlorine at the anode, and various salts, such as sodium hypochlorite, are formed. If sodium hypochlorite is boiled it gives chlorate and chloride. We prepared a mixture of sodium chloride and chlorate, but the percentage of chlorate was too small for the process to be valuable.

Aniline Dyes.—There may be a large field for the application of electrolysis in the aniline industry. A cell was tried with aniline, but it would not conduct. A cell was tried with phenol, but it would not conduct. Potassium hydrate was therefore dissolved in the phenol to make it conduct. A black compound was formed at the anode.

These last experiments are not brought forward as of any value, but they are instances of applications of the dynamo to very different industries. Now that we have the dynamo as a commercial machine, we seem to be resting content with one very small use for it. We use it almost entirely for the electric light. Though it is quite well understood that power can easily be transmitted electrically, the use of motors can hardly be said to be pushed at all. Engineers have only to be shown motors at work to see what beautiful, smooth, and silent-running things they are, and they will be applied in thousands of instances. The dynamo is now being introduced for the treatment of argentiferous copper ; but this is a comparatively small industry. The electro-plating fraternity are a very peculiar people. Though constantly using it they seem to know as little about electricity as medical men. Before electricians can meet them on common ground they must give up talking of the strength of the quantity of current from seventeen Smee cells.

But above all these uses the electrical engineer can supply the chemist with a most efficient and convenient oxidising or reducing agent; unfortunately, however, the electrical engineer does not know what the chemist wants, and the chemist does not know what the electrician can give him.

Every week more young men begin studying to qualify as electrical engineers. Like pins, it is unknown what becomes of them. Would it not pay some of those who are sharp and inventive to take up the study of electro-metallurgy systematically, and to explore that almost untrodden field of the application of the dynamo ?

DYNAMO-ELECTRIC MACHINERY.

By J. Hopkinson, M.A., D.Sc., F.R.S., and E. Hopkinson, M.A., D.Sc.

(Concluded from page 88.)

Appendix.—Added Aug. 17.

Since the reading of the present communication experiments have been tried on machines having armatures wound on the plan of Gramme and with differently arranged magnets ; the experiments were carried out in a closely similar manner to that already described.

Description of Machines.—In these machines [we have not given the illustrations of these machines, the description being sufficient to show how they differ from those illustrated in the preceding part of the paper, *vide* page 42, Nov. 19.] the magnetic circuit is divided. The pole-pieces are of cast iron, and are placed above and below the armature, and are extended laterally. The magnet cores are of wrought iron of circular section and fit into the extensions of the cast-iron pole-pieces, so that the area of contact of the cast iron is greater than the area of section of the magnet. The magnetising coils consist of 2,196 convolutions on each limb of copper wire, No. 17, B. W. G. in No. 1 machine, and 2,232 convolutions in No. 2 machine. The pole-pieces are bored to receive the armature leaving a gap on either side subtending an angle of 41° at the axis.

The bearings are carried upon an extension of the lower pole-piece. The following table gives the principal dimensions of the magnets in No. 1 machine :—

	Cms.
Length of magnet limbs between pole-pieces	26·0
Diameter of magnet limb	8·6
Bore of fields	25·7
Width of pole-piece parallel to the shaft	24·1
Width of gap between poles	8·6

The armature is built up of plates as in the machine already described, and is carried from the shaft by a brass frame, between the arms of which the wires pass.

The principal dimensions are as follows :—

	Cms.
Diameter of core	24·1
Diameter of hole through core	14·0
Length of core over end plates	24·1

The core is wound on Gramme's principle, with 160 convolutions, each consisting of a single wire, No. 10, B. W. G., the wire lying on the outside of the armature in a single layer. The commutator has forty bars. This dynamo is compound wound, and is intended for a normal output of 105 volts 130 amperes, at a speed of 1,050 revolutions per minute. The resistance of the armature is 0·047 ohm, and of the magnet shunt coils 53·7 ohms. There is here no yoke, and consequently A_4 and l_4 do not appear in the equation.

It is necessary to bear in mind that the magnetising force is that due to the convolutions on one limb, and that the areas are the sums of the areas of the two limbs. In calculating induction from E.M.F. it is also necessary to remember that two convolutions in a Gramme count as one in a Hefner-Alteneck armature.

A_1 ;—the section of the core is 245 sq. cms., allowances for insulation reduce this to 220·5 sq. cms.

l_1 ;—this is assumed to be 10 cms., but it will be seen that an error in this value has a much more marked effect on the characteristic in this machine than in the other.

A_2 ;—the angle subtended by the bored face of the pole-pieces is 139°, the mean of the radii of the pole-pieces and the core is 12·45 cms. Hence the area of 139° of the cylinder of this radius is 768·3 sq. cms. ; add to this a fringe of a width 0·8 of the distance from core to pole-pieces as already found necessary for the other machine, and we have 839·5 sq. cms. as the value of A_2.

l_2 is 0·8 cm.

A_3 is 365 sq. cms. (*i.e.*, the area of two magnet cores).

l_3 is 26·0 cms.

A_5 is taken to be 955 sq. cms., viz., double the smallest section of the pole-piece.

l_5 is a very uncertain quantity ; it is assumed to be 15 cms.

The expression already used requires slight modification. Inasmuch as the pole-pieces are of cast iron a different function must be used. Different constants for waste field must be used for the field, the pole-pieces, and the magnet core. We write

$$4 \pi n c = l_1 f\left(\frac{I}{A_1}\right) + 2 l_2 \frac{\nu_2 I}{A_2} + l_3 f\left(\frac{\nu_3 I}{A_3}\right) + 2 l_5 f'\left(\frac{\nu_5 I}{A_5}\right)$$

the function f' is taken from Hopkinson, *Phil. Trans.*, Vol. 176 (1885), p. 455, Plate 52. ν_2, ν_3, and ν_5 were determined by experiment as described below ; their values are

$$\nu_2 = 1{\cdot}05$$
$$\nu_3 = 1{\cdot}18$$
$$\nu_5 = 1{\cdot}49$$

Comparing the curves on Diagram A (p. 40 *ante*) with those on Diagram C, on following page, the most notable difference is that in the latter the armature core is more intensely magnetised than the magnet cores. No published experiments exist giving the magnetising force required to pro-

duce the induction here observed in the armature core, amounting to a maximum of 20,000 sq. cm. We might, however, make use of such experiments as the present to construct roughly the curve of magnetisation of the material; thus we find that with this particular sample of iron a force of 740 per cm. is required to produce induction 20,000 per sq. cm.; this conclusion must be regarded as liable to considerable uncertainty.

The observations on the two machines are plotted together, but are distinguished from each other as indicated. They are, unfortunately, less accurate than those of Diagram A *ante*, and are given here merely as illustrating the method of synthesis.

Experiments to determine ν_2, ν_3, *and* ν_5.—The method was essentially the same as is previously described, and was only applied to No. 1 machine. Referring to Fig. 7, a wire A A was taken four times round the middle of one limb of the magnet, a known current was suddenly passed round the magnets, the elongation of the reflecting galvanometerer was observed; it was found to be 214 scale divisions, giving 107 as the induction through the two magnet limbs in terms of an arbitrary unit. The coil was moved to the top of the limb as at B B—the elongation was reduced to 206 or 103 for the two limbs. We take the mean induction in the magnet to be 105. A wire was taken three times round the whole armature in a horizontal plane as at C C; the elongation observed was 222 divisions or 74 in terms of the same units. A wire was taken four times round one half of the armature as at D, D; the elongation was 141, or induction in the iron of the armature 70·5, whence we have

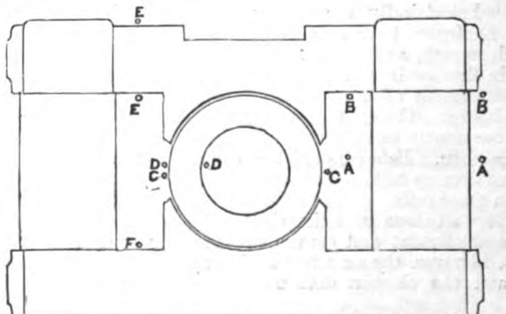

FIG. 7.

$$\nu_2 = \frac{74}{70 \cdot 5} = 1 \cdot 05.$$

Digitized by Google

It may be well to recall here that ν_2 is essentially dependent on the intensity of the field; strictly the line B on Diagram C should not be straight but slightly curved.

Four coils were taken round the upper pole-piece at E E; the elongation was 159, giving 79·5 on the two sides. Coils at F F give a higher result, 87·5, owing to the lines of induction which pass round by the bearings of the machine, and across to the upper ends of the magnets—ν_2 is taken to be

$$\frac{83 \cdot 5}{70 \cdot 5} = 1 \cdot 18.$$

The method and instruments were those already described, excepting that the current was measured by a Thomson's graded galvanometer, which had been standardised against a Clark's cell in the position and at the time when used. The resistance of leading wires and galvanometer was 0·034 ohm, the series coils introduced for compounding the machines were also brought into use, and the losses due to their resistance find a place in columns XII. and XIII. of the following Table III., in which column I. is lead of brushes of the dynamo, positive for the generator, negative for the motor; column II., revolutions per minute; column III., deflection of spring in grammes; column IV., watts by dynamometer; column V., volts at terminals of generator; column VI., amperes in external circuit; column VII., rheostat resistance; column VIII., watts in generator armature; column IX., watts in motor armature; column X., watts in generator shunt magnet coils; column XI., watts in motor shunt: column XII., watts in generator series magnet coils; column XIII., watts in motor series; column XIV., watts in external resistances; column XV., total electrical power of generator; column XVI., half the sum of losses unaccounted for; column XVII., total mechanical power applied to generator.

Table III.

1	17·5°	1098	7711	4419	100·1	139·0	∞ty	955	895
2	5°	1094	2722	1554	103·8	41·2	18·8	105	78
3*	0°	1144	1814	1083	104·7	7·85	0	11	3

No. of experiments.	X. Watts.	XI. Watts.	XII. Watts.	XIII. Watts.	XIV. Watts.	XV. Watts	XVI. Watts.	XVII. Watts.
1	372	0	497	464	657	16,395	289	16,684
2	400	138	55	41	148	5,015	294	5.309
3*	395	409	6	1	2	1,637	128	1,765

* In this experiment the direction of the current had become reversed, and No. 2 machine was generator.

Table IV.

No. of experiment.	Generator armature.	Generator shunt coils.	Generator series coils.	Other losses.	Effici'ncy of generator	Effici'ncy of motor.	Effici'ncy of double conversion.
1	5·8	2·2	3·0	1·9	87·1	89·0	77·5
2	2·0	7·5	1·0	5·5	84·0	92·0	77·7

Table IV. gives the losses and efficiencies as percentages in exactly the same way as in Table II., excepting that another column is introduced for the loss in the series coils of the magnets of the generator.

The core of the armature contains about 6,500 cub. cms. of iron. Hence energy of magnetising and demagnetising when the speed = 1,100 revolutions per minute $= 6{,}500 \times \frac{1{,}100}{60} \times 13{,}356$ in ergs per second = 159 watts.

In conclusion, we desire to express our indebtedness to Messrs. Mather and Platt, by whom the machines we have used were manufactured, and who, in placing the same at our disposal, together with all facilities for carrying out our experiments at their Salford Iron Works, have enabled us to put theory to the test of experiment on an engineering scale.

THE TESTING OF DYNAMOS AND MOTORS.

At the City and Guilds of London Institute, Exhibition-road, during the months of February and March, Prof. Ayrton will give a course of seven practical demonstrations in the dynamo rooms and laboratories of the Institution. Each demonstration will be given twice, once on the Friday, at 5 p.m., and again on the following Wednesday, at 5 p.m., in order that all who attend the course may take part in the experiments. After Ash Wednesday, on which day the college will be closed, the same demonstration will be given on the Wednesday and Friday of the same week. In addition to making the measurements referred to in this syllabus, and describing in detail the principles of each experiment, Prof. Ayrton and his assistants will, *before* each demonstration, give explanations of the more elementary parts of the subjects taken up in the demonstrations.

Demonstration No. 1 (Friday, February 4th. Repeated Wednesday, February 9th. 5 p.m.).—*Series Dynamo:* Practical modes of measuring the power given out by a series dynamo. Experimental determination of the increase of resistance, and the waste of power due to the self-induction of the armature. Measurements of the E.M.F. of the dynamo, when any current whatever may be passing through the armature, without knowing the current, resistance or self-induction of the armature. Experiments to test whether a series dynamo has a critical speed. Experimental determination of the true law of variation of E.M.F. with speed, either when the current is constant or when the resistance is constant. Experiments on the resistance in which the maximum useful work is done by a series dynamo running at a given speed.

Demonstration No. 2 (Friday, February 11th. Repeated Wednesday, Februaiy 16th. 5 p.m.).—*Shunt Dynamo:* Measurements of the useful power given out by a shunt dynamo. Experimental determination of the effect produced by varying the resistance of the shunt. Finding the true form of the curve connecting potential differences and current in the outside circuit, also the true form of the curve connecting the current and E.M.F. in the armature of a shunt dynamo. Experiments on the alteration of the general shape of the characteristic curve by altering the ratio of the ampere turns on the armature and field-magnet.

Demonstration No. 3 (Friday, February 18th. Repeated Friday, February 25th. 5 p.m.).—*Compound Wound Dynamo:* Combining a series and a shunt dynamo to obtain constant potential difference, or constant current. Compounding a dynamo. Experimental determination of the action of the shunt coil and of the series coil separately, and of the effect produced by the saturation of the iron cores of the field-magnet on the combined action of the shunt and series coils. Experiments on running a compound wound dynamo at different speeds.

Demonstration No. 4 (Wednesday, March 2nd. Repeated Friday, March 4th. 5 p.m.).—*Self-Induction and its Measurements:* Experiments on the effects of self-induction on an intermittent direct current with not very short period of intermittence. Alteration of effects when the period of intermittence is very short. Experiments on the effects of self-induction on an alternating current, and of the variation of the effects with the period of alternation. Unit of self-induction. Modes of measuring self-induction. Employment of commercial instruments for measuring self-induction, and the results obtained.

Demonstration No. 5 (Wednesday, March 9th. Repeated Friday, March 11th. 5 p.m.)—*Alternate Current Dynamo:* Useful power given out by an alternate current dynamo. Experimental determination of the speed correction to apply to a high resistance dynamometer used as a voltmeter, as well as the small speed correction of reading of a low resistance dynamometer used as an ammeter. Error in the common mode of measuring the power given out by an alternate current dynamo. Proper mode of measuring with an electrometer. Commercial form of electrometer for the purpose. Variation of the useful power with the external resistance and speed.

Demonstration No. 6 (Wednesday, March 16th. Repeated Friday, March 18th).—*Mechanical Measurement of Power:* Power given to a dynamo, measuring with a transmission dynamometer. Useful power given out by a motor, measuring with an absorption dynamometer. Determining the efficiency of a dynamo and of a motor, when running at different speeds and absorbing different amounts of power. Measuring the power wasted in a dynamo and motor by—1. Mechanical friction; 2. Magnetic friction; 3. Magnetic Lag; 4. Heat produced by currents; 5. Self-induction. Waste of power in its transmission from the engine to the dynamo, or from the electro-motor to the machine driven by it. Modes of diminishing this waste by the use of special methods of coupling the machines between which the power is transmitted.

Demonstration No. 7 (Wednesday, March 23rd. Repeated Friday, March 25th).—*Measuring Joint Efficiency of Coupled Dynamo and Motor:* By mechanically supplying the power wasted in the dynamo and motor combined, and measuring with a transmission dynamometer the power so supplied. By employing accumulators to furnish the total power wasted and measuring electrically the power furnished for this purpose.

The programme of the Institution and the calendar containing full particulars of the work of the Institnte may be obtained at Exhibition-road, S.W., or at the office of the Institution, Gre:ham College, E.C. The fee for the course is £1. 11s. 6d.

THE TELEGRAPHIC BREAKDOWN.

The snowstorm of Sunday, December 26th, will long be remembered as having proved more disastrous to the telegraph system of this country than any which has been hitherto experienced. On Monday morning (says *The Times*), out of nearly 500 wires connecting places outside the metropolis, only six were left standing. There was one to Belfast, one to Edinburgh, one to Glasgow, one to Liverpool, one to Manchester, one to Birmingham, and one to Dublin. Later in the day a second wire was got through to Liverpool, and a second to Birmingham, and by means of the latter communication was opened with Bristol. The work of repairing the damage was undertaken without delay, and on Wednesday the number of overhead wires in use was increased from nine to 29, additional lines being opened to Glasgow, Liverpool, Manchester (three being secured to each city),' Birmingham, Leeds, Cardiff, Derby, Southampton, Salisbury, Guildford, St. Albans, Uxbridge, and several other places of less importance. In the suburbs of London no fewer than

Digitized by Google
REESE LIBRARY OF THE UNIVERSITY

250 wires were broken; but no interruption whatever occurred to the wires carried through underground pipes over what may be described as the commercial area of London. The boundaries of this district can hardly be defined in general terms, for the reason that the system of underground pipes has been developed by a series of spurs running in different directions. For instance, on one side of the City the pipes have been laid as far as Bromley, on another side they reach Barnet, while in a third they extend to Uxbridge. Many intermediate places have to depend for telegraphic communication solely upon overhead wires, and it is these which suffered under the pressure of snow and wind on Sunday night. The Stock Exchange has lost every single wire which it possessed, and most serious inconvenience was on Wednesday the result. The Submarine Telegraph Company is in an equally unfortunate position, and the services with France, Belgium, and Holland are entirely suspended. As far as the officials of the Post Office have at present been able to ascertain, the greater part of the destruction has occurred within a radius of 100 miles from London. At Maidenhead the wreck is complete, every pole and wire having been thrown to the ground, while the line from London to Lowestoft has also been dismantled. Wires carried along high roads and railways have suffered alike disastrously, and iron posts broke as often as those of wood. North of Birmingham and in Scotland and Ireland the wires were not affected by the storm, and local communication is going on as usual. All sorts of expedients have been adopted by the authorities of the Telegraph Department with the object of minimising the effects of this wholesale derangement. Thus the service between London and Cardiff has been resumed *viâ* Birmingham. Aid has been summoned from parts of the country where the violence of the storm was not experienced, and gangs of men were yesterday sent to assist those stationed in the southern and eastern districts. Application has also been made to the War Office, and it is expected that the staff engaged in the work of restoration will be augmented not only by an increased number of Royal Engineers, but by members of the railway, field telegraph, and other corps in the Army. It is the practice of the Telegraph Department to keep in each district the name and addresses of competent men who can be called upon in emergencies to repair the wires, and these, too, are being set to work wherever their services can be secured. In the meantime thousands of telegraphic messages have to be sent by train. On Monday—although it was Boxing Day—20,000 messages were received at the Central Telegraph Department, and by far the greater part of them had to be forwarded by rail, being made up into special parcels, and despatched by the ordinary trains. Over 6,000 messages passed between different parts of London, and owing to the immunity which the underground wires enjoyed in the general wreckage they were not in any way delayed. The overhead wires which have been damaged in London are as a rule those of one or other of the telephone companies, and not of the Post Office, the underground system having in recent years been extended to such a degree that every main line in the metropolis, as also in the large provincial towns, is now carried in pipes laid below the street pavement. Of the extent of the disorganisation the following communication, which was issued on Monday by the Secretary to the Post Office, will give some idea:—"Telegraphic communication totally interrupted from London to the east, south east, south, and south-west of England. Partial interruption to the north of England, Scotland, and Ireland, with heavy delay, but the communication in the north of England, Scotland, and Ireland is generally good. There is no delay to the inner London local traffic. The Submarine Company give notice of total interruption to the Continent."

In Walworth, Newington, Blackfriars, Southwark, Bermondsey, Rotherhithe, and other adjoining districts, there was scarcely a set of overhead wires intact. In all the principal thoroughfares of the neighbourhoods referred to, hundreds of wires were drooping across from one side of the road to the other, so low that police officers were told off to warn drivers of the danger. Besides the drooping wires some hundreds which actually fell to the ground were cut by the police and secured in a place of safety. In some cases, on the telegraph poles giving way, the roofs of houses were uplifted and numberless chimney-pots knocked over, some of them falling into the street. In the City the telegraph and telephone wires have suffered most severely. In the area stretching from the Mansion House to the Baltic the great network of wires and cables were either hanging low down under their weight or snapped asunder altogether.

All telegraphic communication from London and the provinces to the central and southern parts of Europe by the ordinary routes has been interrupted. Numerous messages from those countries have been received by the lines of the Great Northern Telegraph Company, who are prepared to receive outward messages at the higher rates as prescribed by the International Telegraph Convention if marked "*via* Northern."

The telegraph wires on the South-Eastern, London and Brighton, and London, Chatham, and Dover lines were pulled down in all directions. At the bridge crossing the roadway at St. John's (South-Eastern Railway) a telegraph post, fixed by iron clamps to the wall, was pulled by the weight of snow on the wires down on to the railway, bringing with it about 12ft. of solid masonry and brickwork.

At Dover the damage to the telegraph wires has been most extensive and disastrous, the town being entirely cut off from communication with any towns except one or two within a radius of six or seven miles. There are three sets of wires from Dover—those of the General Post Office, the South-Eastern Railway, and the London, Chatham, and Dover Railway. All of these suffered alike, the London and Chatham lost communication except as far as Faversham, and Deal and Folkestone were the eastern and western extremities of telegraphic communication yesterday morning, all telegrams received at the post office being sent by train to London and places at a distance.

The telegraphic service at Cambridge was blocked all round, and considerable damage was done by the breaking of the telephone wires. By 10 o'clock on Sunday evening communication between Birmingham and London had entirely ceased, all the wires being down along the canals, roads, and railways. Communication with all western and northern districts was also stopped, as well as with Scotland, Ireland, and the Continent. There was a total cessation of telegraphing from 10 o'clock until about 2 yesterday morning, when communication between Birmingham and London was successfully established *viâ* Manchester. At eight o'clock in the evening the telegraph service at Bristol was completely suspended, and after that hour there was no communication with the districts beyond the city, and all telegrams were refused by the officials. The line of the Great Western Railway between Reading and Oxford was blocked by fallen telegraph poles; but communication was soon restored and trains were run, though with a good deal of irregularity, owing to the damage done to the telegraph wires. In many places the telegraph poles were broken in two, and almost all along the line of the Great Western Railway between London and Reading the wires had either been snapped or the poles had fallen across the line. Large numbers of men were to be seen at intervals busily engaged in removing the obstructions to traffic, and where it was possible repairing the damage occasioned by the storm. Salisbury and other towns have been completely cut off, telegraph poles and wires in all directions having come to grief. The last train from Uxbridge for West Drayton Junction, on the Great Western Railway, soon after its arrival at the latter station, was delayed for the night by a network of wires, the engine driver and stoker narrowly escaping serious injury. The last up train on the main line was stopped at the same point, many of the telegraph poles between there and London having fallen with the wires across the railway and so caused a dead block. The telegraph poles had in many instances snapped off short, and more than a hundred were reported to be down between Paddington and Slough, exclusive of those on the branch lines, where the damage was also serious. Between Bristol and Bath as many as 50 poles were broken clean off by the force of the wind. A train from Bristol to Salisbury on Sunday evening came into collision with a telegraph post which was lying across the line, but fortunately only one passenger was hurt, and his injuries were not of a serious nature. The same train afterwards encountered so many fallen poles that it was deemed unsafe to proceed, and at Heytesbury the passengers were made comfortable for the night in the waiting-room. Further west the damage was very great, Yeovil, Taunton, Exeter, and most of the smaller towns in Devon and Somerset were entirely cut off from communication. At Plymouth, however, no snow fell, and not *a single wire was damaged.*

CONCERT BY THE STAFF OF THE EASTERN TELEGRAPH COMPANY.

For the last five years a concert has been given in the East End of London by the staff of the Eastern Telegraph Company, assisted by friends, for the purpose of raising funds to provide Christmas dinners for the poor in their own homes. This year the concert was given in the Great Assembly Hall, Mile End-road, E. (Mr. F. N. Charrington's), an edifice of palatial proportions, at which Sir JAMES ANDERSON took the chair. There were about 3,000 persons present.

In opening the proceedings the chairman said: My part of the programme this evening is a very simple one. My business is to act as a sort of figurehead, and introduce those ladies and gentlemen who have so kindly volunteered to help us. At the same time I have something to say before we commence the programme, but I will not occupy you more than three or four minutes. One cannot come here to a hall like this without a certain amount of reflection and going back over one's own lifetime and thinking what it all means. Ladies and gentlemen, I can go back so far as to be able to tell you that I rowed in a boat race on the Queen's coronation day—that is a long time to go back—and a few years after that I had in my vocation of life (that of a sailor) to be frequently in the Docks in this neighbourhood, and I can tell you that in those days there was no such great hall as this in all London for this kind of entertainment, neither East, West, North, nor South, and we had to go a long way from the Docks if we wanted to pass an evening of the kind. In those days a walk from the West End to St. Katherine's Docks took almost as long as it does now to communicate with Australia or California. Now, I could not help thinking, as I came into this hall a few minutes ago, how much you and I and all of us are indebted to the gentleman who had the heart to build it (applause) for the benefit of his fellow citizens. I certainly honour that gentleman, although I have never seen him, for the great good he has done—more, I think, than he is aware of (applause). Let me say a few words, and tell you what these reflections gave rise to in my mind. It is a long time to carry one's memory back to the coronation of our good Queen, and it is hardly possible to tell the story of the great and marvellous changes that have occurred since then. We have had steam, electric telegraphs, iron ships, instead of the wooden ships which one used to travel in in those days, and the result of all this is that those great factors—railways, steamships, and telegraphs—have, I believe, changed the whole future of the world. Since the days of which I speak the population of the United Kingdom has doubled, and if it had not been for these great changes I do not know what would have been the result. As it is, we have sent ten millions of our countrymen, old and young, to spread the English name and language all over the world. This could not have been so but for the improved communication by steam to our colonies all over the world; and yet the cry is that there are too many of us in these islands, more than could have been fed fifty years ago. But nowadays it is as easy to get to our colonies and to trade to all parts of the world as it was to trade when I was a boy between Liverpool, Glasgow, or Birmingham. I see before me to-night lots

Digitized by Google

of young people, and I want to tell you this—and bear it in mind, for it will do you no harm—the changes that I have seen, great as they have been, are to my mind nothing to what you are going to see by-and-bye. You will be able to tell the young folks of the period, 25 or 35 years hence, of all the great changes that have taken place since the days of Queen Victoria's Jubilee. You will tell them of the introduction of free education, of greater social intercourse between all classes, of science matured, and such things as the electric light, just coming into general use, and you will have the advantage of knowing which of all the great factors I have referred to has made the greatest mark upon the past generation of your own life time: for at present we are too near, too mingled with the changes which science is making, to realise the relative value of one more than the other. But my conviction is that you young folks are on the threshold of a great social revolution of a very stupendous character. If you will watch it, and work and wait, and not be too anxious about the result, and not too eager to do anything special, but just to do the best you can, many of you may live to see great changes, and then I hope you will take care to act only as will add to the glory of this nation and its prosperity. It is not given to everyone, of course, to be great nor to be very conspicuous, but everyone in my opinion can help, and those who work bravely and patiently in the vocation in which they are called can do something to help to make the history of this land. No nation can be great which has not a vast crowd of makers of unwritten history, and upon the youth of this nation rests the duty of keeping the history of this country as bright in the future as it has been in the past (applause). And now, ladies and gentlemen, let me say what great pleasure it gives me to be present to-night in aid of this fund to provide Christmas dinners for those who are not so fortunate as we are. There are always some who are struggling, as it were, against a strong tide and hardly managing to keep afloat, and there will always be a great number who only make leeway. I am here to-night with a number of young men who are pulling in the same boat as myself in our daily work with the hope that we shall do some little good; but I may not detain you longer, the programme is long one, and I will only ask you to join with me in giving hearty thanks to those who have kindly come forward to assist (applause).

The speech, which was listened to throughout with the greatest attention, was then followed by a capital concert, all the *artistes* being well received. Amongst the vocalists were Mr. W. J. Finnis, Mr. J. F. Harrap, and Mr. Leyten Barker. Miss Maude Snell sang in perfect style "Esmeralda," for which she was rapturously encored. Mr. A. R. H. Mackay gave "The Lost Chord" on the cornet, and was very well received. The performances of the Apollo Orchestral Band were very warmly applauded. The palm of the evening, however, was certainly carried off by Mr W. A. Owen, who, in reciting "Asleep at the Switch" and "A Street Arab's Story," created great enthusiasm. Mr. Arthur Briscoe presided with great ability at the piano and organ.

This entertainment was by far the most successful yet given in connection with this charity, which was attributable in a very large degree to the genial presidency of Sir James Anderson. By means of this concert and other contributions about 200 families, representing about 800 persons, were supplied with the requisites of a good substantial Christmas dinner on Christmas Eve, under the superintendence of the chairman of the dinner fund, Mr. E. H. Kerwin.

Too much praise cannot be given to the staff of the Eastern Company for supporting so heartily this good work for the East End poor. The concert and dinners are organised by Mr. Thos. Richardson.

COMPANIES' MEETINGS.

New Telephone Company (Limited).

The second ordinary general meeting of the shareholders of this Company was held at the offices of the Company, 4, Great Winchester-street, E.C., on Saturday, 18th inst., Lord Thurlow (the Chairman) presiding.

The CHAIRMAN, in moving the adoption of the report, stated that the Company had been successful at the commencement of its business in obtaining the license of the Postmaster-General. The telephone which the Company supplied to the public was the invention of Dr. Silvanus P. Thompson. At first some little disappointment was experienced when it was found that the instrument did not prove so efficient for exchange work as had been anticipated. Since then improvements had been introduced into the instrument, which rendered it thoroughly satisfactory, and he (the Chairman) firmly believed that the Company now possessed an instrument which was distinct and clear in its articulation, was a most valuable instrument for long distances, and was, in fact, second to none in the world. Although the Company had only quite recently commenced selling telephones to the public, it was encouraging to be able to record that their sales were steadily increasing. Their telephones were now being freely sold in all the principal English and Scotch towns and provincial districts, also in Ireland and in Wales, and testimonials proving their efficiency were daily coming in from customers. With regard to the financial position of the Company the Chairman was happy to say that it was eminently sound. In reference to the future policy of the Company, it was intended at the beginning of the new year to form a large and powerful company, and, inasmuch as the Company's patents were now known to be very valuable property, he felt convinced that there would be no difficulty in the formation of such a company. Moreover, the circumstances of the Company's business rendered it necessary that a large company which would be competent to further develop the business now established should be formed without delay. In order to be successful on a large scale, the Company must open exchanges, and these could not be efficiently organised except by a powerful company. Numerous applications from towns and cities in the United Kingdom had been received by the Company with reference to the establishment of exchanges, and it would be the object of the new company to deal with these applications. In one of the most important installations undertaken by the Company, there was some difficulty in overcoming the induction caused by the immediate proximity of an electric railway, but the installation was at last successfully and satisfactorily accomplished. On the line referred to, another telephone, in extensive use in this country, was tried, but the induction was very much more perceptible than with the Company's instruments. Their telephones were working perfectly in noisy factories in the north of England, where the circumstances were far from favourable for the good working of a telephone.

Dr. THOMPSON then addressed the meeting, and explained the improvements which had been made in the instrument. These improvements, he said, were nearly all of them mechanical details, in developing which Mr. John S. Sellon had kindly rendered the most valuable assistance.

The adoption of the report was seconded by Sir JAMES M'GAREL-HOGG, and unanimously agreed to, after which the retiring Directors—Sir Daniel Cooper, Bart., and Mr. J. Irving Courtenay were re-elected. The re-election of the auditors—Messrs. Deloitte, Dever, Griffiths, and Co., having been also agreed to, a vote of thanks to the Chairman and Directors of the Company concluded the business of the meeting.

Simplex Electrical Syndicate (Limited).

The first ordinary general meeting of the shareholders of this Syndicate was held on the 29th inst. at the offices, 109, Farringdon-road, London, under the presidency of Mr. C. L. W. FitzGerald.

The SECRETARY (Mr. W. J. Milne Menzies) read the notice convening the meeting, and the minutes of the statutory meeting were taken as read, and signed by the Chairman. The report of the Directors was taken as read.

The CHAIRMAN: Gentlemen, this Syndicate, as you are aware, was formed for the purchase and working of certain patents, the principal being for an arc lamp and for an electric printing machine or tape record. When we bought these patents we of course thought, as a good many others would have thought, that we should find a very ready sale of our arc lamp for two reasons, one being that it was an extremely steady light, and the other on account of its, I may say, extraordinary cheapness. On going a little further into the matter we discovered that nearly everyone who was a large manufacturer had a patent of his own for an arc lamp, and the result was that, instead of, as we expected, selling those arc lamps to any great extent, we found it would be absolutely necessary for us to go into installations. I need not remark that the capital of this Company was by no means adequate for that, and therefore the Board had to consider what was best to be done. We have come to the conclusion that the best thing we possibly could do is to use our utmost endeavours to sell the patents we have taken out for the arc lamp. We have taken out patents of this lamp in the United Kingdom, Austria, Belgium, France, Germany, New South Wales, New Zealand, South Australia, and Victoria. We have come to the conclusion, as I have said, that it will be the best thing for us to try and sell these patents, either for a lump sum, or else under a system of royalties, and we are using our utmost endeavours to effect the sales of these patents. I should tell you that we have had trials at various places. Perhaps the most satisfactory trial that we have had has been at the General Post Office, St Martin's-le-Grand, and through that we have received an order for six small arc lamps on trial. We are at this moment testing lamps to send to the Edison Company of Germany in Berlin, and I hope that when they have received these lamps and tried them they may feel disposed to purchase the patent for Germany. In addition to that we have had trials at Vienna and Paris, and both, I think, have been satisfactory, though as none of our people were there we cannot say exactly what happened These trials were made by the Imperial Continental Gas Association. I should further tell you that we had a trial at the works of the Gülcher Electric Light and Power Company, and the Chairman, the managing director, and a number of people who were present at that trial expressed themselves very much satisfied with the lamp. Moreover, that company made a proposal, on certain terms, for the purchase of the lamp, but your Directors did not consider it was good enough, and, therefore, the matter dropped for the time being. The next point that I consider of great importance is that we have got permission to instal five arc lamps at the Liverpool-street station of the Great Eastern Railway. This, I believe, will probably result in our being able to sell some lamps to that company, and through them no doubt we shall eventually sell lamps to other railway companies. Almost by accident, as I may say, we had the offer made to us to finish the lighting of the hospitals, on the ships and on shore belonging to the Metropolitan Asylums Board at Dartford. As this work, of course, did not require a very large capital we were only too happy to do it, and we finished the work successfully, and have been paid for it. There is no doubt that our lamp is one that can be made very cheaply, and as far as your Board are concerned they undoubtedly think the lamp is one of the steadiest, if not the steadiest arc lamp in existence. It comes to this, therefore, that probably some one or two companies may purchase this patent, and if it is purchased at a royalty it will of course be a very good thing for the shareholders. We have done, as you can see on examining the accounts, all we can to keep down the expenses. The large item, of course, is wages. That certainly is a very large sum in proportion to the other items, but we cannot possibly do without workmen, so we can say no more on that head. As far as our stock and plant are concerned, I think we have taken them at a low valuation. We have still a considerable sum in hand—

Digitized by Google

£1,462. I may add that last week we placed in the hands of the Anglo-American Brush Corporation one of our arc lamps to test, and but for the telephone wires having broken down, I should have inquired to-day before this meeting as to whether they had done anything with that lamp. I will now propose:—"That the report, balance-sheet, and accounts received from the Directors be adopted." But before I put the resolution I shall be very happy to answer questions if gentlemen have any to put.

Major H. T. G. FitzGerald inquired at what price the "simplex" lamp could be made.

The Chairman: We consider that the lamp can be made for 30s. to 35s. without the globe. The cost of other lamps varies from £5 to about £12. I presume that is also without the globe, but I am not quite certain.

Mr. Richard Van Zeller then seconded the resolution, which was carried.

The Chairman said that they had to consider the question as to the time of holding their future meetings. The present report was for a term of ten months up to the 30th ult. He thought that a good time for the termination of their financial year would be the 31st October. They had had rather a "scramble" in getting the present report out, as the time was very awkward owing to the Christmas holidays. He thought it would be well in future to let their financial year end on the 31st October and to hold the annual meeting in November or early in December. So far as the current year was concerned, that would give them eleven months' working. He did not think it was necessary to submit a resolution on the point, but if what he had said met with their approval he would enter it on the minutes. In reply to a shareholder, he said that if they were to decide on an earlier period for the meeting—say, in September or August—everyone would be away for his holidays.

Mr. Thornton said that October would be a very busy month for the Company in connection with the question of manufacturing, and he therefore thought there would be some difficulty as regarded the stocktaking.

The Chairman said he believed there would be no difficulty, and if they were busy he might have the satisfaction of telling the shareholders something that would be pleasant for them to hear.

The suggestion having been approved,

Mr. Van Zeller proposed, and Mr. R. E. Bateman seconded, the re-election of Mr. FitzGerald to his seat at the Board.

On the motion of Major FitzGerald, seconded by Mr. G. A. Mason, Mr. R. E. Bateman was also re-elected a Director.

Mr. Arthur E. Green having been re-elected auditor,

Mr. Mason proposed, and Mr. Thornton seconded, a vote of thanks to the Chairman, which was carried unanimously.

The Chairman, in acknowledging the vote, assured the shareholders that the Directors would do all they could to promote the welfare of the Company.

The shareholders were afterwards invited to inspect the lamps and tape record.

The Pilsen, Joel, and General Electric Light Company (Limited and Reduced).

The fifth ordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel, on the 23rd inst., under the presidency of Sir Rawson W. Rawson, K.C.M.G., C.B.

The Secretary (Mr. W. H. Trentham) read the notice convening the meeting, and the report of the Directors was taken as read. It stated that the resolution recently passed for a further reduction of the Company's capital had been duly confirmed by the order of the Court. The accounts and balance-sheet embraced the period from 30th June, 1885, to 30th June, 1886, and the capital therefore appeared as it stood on the latter date. The amount of calls in arrear was reduced during the year by nearly £500, and the Board had since felt it their duty to forfeit the shares of those still in default. The number so dealt with was 3,517 shares, leaving 24,483 partly paid up shares outstanding. The paid up capital of the Company therefore at present stood at £30,828. 15s., of which £30,603. 15s. was represented by £1. 5s. per share now credited on the 24,483 outstanding partly paid up shares, and £225 by the 100 fully paid up shares now reduced to £2. 5s. each. They congratulated the shareholders that during the period dealt with in the accounts (the first year's working at the new factory) a net profit of £1,111 was realised. The Board had, subject to the sanction of the general meeting, declared a dividend on the present paid up capital of the Company, at the rate of 8d. per share on the partly paid up shares, the equivalent amount in respect of the fully paid up shares being 14d. per share. This payment would absorb £822, leaving a balance of £289 to be carried forward. Mr. Trentham continued his manifold duties to the complete satisfaction of the Board. The revenue account showed that the receipts, by sundry sales, had been £3,203, and by rents, &c., from installations, £3,291, while under the head of "sundry receipts" (principally royalties—£368) a revenue of £548 had been obtained.

The Chairman: I will now move the first resolution, which is the adoption of the report, with the accounts and balance-sheet for the year ended June 30, 1886. I need not detain you long in submitting that proposal. When we met on the last occasion, in the middle of 1885, we undertook, at a time of difficulty, to carry on the affairs of the Company in such a manner that we should not, at all events, lose any of the remaining capital, and that we should keep the affairs of the Company in such a condition that whenever electric lighting was likely to come into general use, by some Act of Parliament, which would lead to street lighting, and consequently the development of the lighting by arc lamps, which is our principal patent, we might take advantage of the improved times. With regard to the difficulties which have attended the question of incandescent lamps, as soon as the contest between the Swan and Edison Company and the firm of Woodhouse and Rawson on the subject of the rights of the former Company is settled, we have reason to hope that the electric light will take a decided development. We have, therefore, not wasted our small funds in making attempts at development which had not succeeded up to last year, and which we had no reason to hope would result more favourably; but we have kept down our expenses to the lowest ebb. We have availed ourselves of every occasion of making a profit, and almost unexpectedly to ourselves we are able to submit a balance-sheet showing an actual profit during the past year ended June, 1886, which will enable us to offer a dividend to our shareholders. I may also add that affairs have gone on quite as favourably since, and that the prospects of the remaining half year are equally favourable. We, therefore, have reason to expect that this is the commencement of a resuscitation of the interest of the Company, though the capital which was embarked in it at first has been absorbed—lost, in fact—for unless something exceptional occurs we cannot, of course, look forward to replacing that capital. Upon the reduced capital, however, for which we have obtained our order, and which now stands at £25,000, we hope to maintain a fair profit, which will enable us to offer a reasonable dividend, and perhaps in the future even more than a reasonable dividend—a large dividend—on that reduced capital. I therefore have great confidence in asking you to accept and adopt this report and balance-sheet.

Mr. Thomas Weyman (a shareholder) seconded the motion, which was carried unanimously.

The Chairman next proposed the declaration of the dividend of 8d. and 14d. a share, as mentioned in the report of the Directors. The shareholders, he said, would see that the Directors, acting like men of business, had not attempted to divide the whole amount of profit and increase the dividend by 1d. or 2d. a share. They had proposed for division what they considered money actually and fairly earned, leaving something towards next year, with the view of being able to divide at least an equal amount then.

Mr. James Fyfe (a shareholder) seconded the motion.

A Shareholder: Is the amount of £3,500 still invested in consols?

The Chairman: £4,500. He then put the motion, and it was carried unanimously. Continuing, he proposed the re-election as a Director of Mr. Horace W. Scriven.

Mr. Wm. Mogg (a shareholder) seconded the resolution, which was carried unanimously.

On the motion of Mr. Fyfe, Messrs. Broom, Hays, and Akers were re-elected auditors to the Company.

The Chairman, in announcing the conclusion of the business of the meeting, assured the shareholders that the Directors had the interests of the Company at heart, and that they would do their best to secure a good dividend and the prosperity of the Company.

On the motion of Mr. Akers a vote of thanks was passed to the Chairman and Directors, and the proceedings then terminated.

NOTES.

BRO. M——S.—Hearty good wishes. No. 1,768.

TO OUR READERS.—A happy, busy, and prosperous year.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 31st amounted to £3,538.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending 31st December were £4,590.

THE BALLOON SOCIETY.—A lecture on "The Electric Telegraph Jubilee" is announced to be delivered at the Royal Aquarium by Mr. Thomas Moy, C.E., on Friday evening next at eight o'clock.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending December 31st were £2,869, after deducting the fifth of the gross receipts payable to The London Platino-Brazilian Telegraph Company.

ELECTRIC LIGHT IN THE NAVY.—The Admiralty has recently issued a circular, requiring that all ships provided with electric search lights shall exercise their crews twice each year at target firing and defence against torpedo boats under the search light.

THE GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of the above company are as follows:—Receipts for December, 1886, £19,600; 1st January to 31st December, 1886, £258,600; corresponding months, 1885, £284,720; corresponding months, 1884, £276,280.

ELECTRIC LIGHTING OF MILAN CATHEDRAL.—It is stated that the Pope has at length overcome his long-entertained scruples about admitting so heretical a power as electricity into the sacred precincts of Milan Cathedral, and has consented to its being lighted electrically.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of December was 3,695, estimated to produce £3,100, against 3,023 messages, producing £2,448 in the corresponding month of last year. The traffic receipts for the month of September, estimated at £2,250, realised £2,272.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—This company have declared an interim dividend for the quarter ended 30th September last of 2s. 6d. per share, free of income-tax, payable 15th January.—The traffic receipts of this company for the month of December amounted to £40,539, and to £34,785 in the corresponding period of 1885.

THE POSTAL TELEGRAPH REVENUE.—The Revenue Returns for the nine months ended December 31, 1886, show a decided improvement in the receipts derived from the telegraph service. The increase on the corresponding period in 1885 is £40,000, the major portion of which has been earned in the last quarter of the year just ended. For the whole year the increase is £30,000, the figures being £1,780,000, against £1,750,000 for 1885.

SALE OF PLANT AT SOUTH KENSINGTON.—We would call the attention of our readers to the announcement which appears in our advertisement columns of the forthcoming sale, by Messrs. Wheatley Kirk, Price and Goulty, of the engines, boilers, dynamo machines, arc and incandescent lamps, and general electrical plant and instruments, which were used for the electric lighting of the Indian and Colonial Exhibition.

THE BURMESE TELEGRAPHS.—The *Indian Engineer* says that the telegraph line connecting Bangkok with Burmah has been working satisfactorily in spite of the difficult country through which it had to be taken. It will shortly be duplicated by another, crossing the hills between Siam and Burmah at Myawadi, to the north of the present line. Another line is in course of construction, passing from the capital down the east side of the coast of the gulf.

LINDAL-IN-FURNESS.—The *Whitehaven News* mentions that Messrs. Harrison, Ainslie and Co., of Lindal Moore Mines, have extended their system of electric lighting to their Lindal Cote Works, and in doing so have placed three lamps in prominent situations in the village. A storage chamber has been constructed in the new church, and a number of lamps have been put up, and it is expected that the church will shortly be lighted with electricity.

THE PRICE OF CARBONS IN AMERICA.—There are nine large companies engaged in the manufacture of carbons in the United States. Seven of these have recently entered into a mutual agreement respecting the price of their wares, and have issued a joint circular to their customers. The prices agreed upon are quoted per 1,000ft. as follows:—$\frac{7}{16}$in. by 12in. at $12, $\frac{1}{2}$in. by 12in. at $15, and $\frac{5}{8}$in. by 12in. at $25, shorter lengths and odd sizes in proportion, plus a stated percentage.

A FRENCH INSTALLATION.—The Eldorado Theatre and Café has recently been supplied with an installation of 35 arc lamps. To provide current for this number of lamps it has been thought desirable to employ *seven* A Gramme machines, each capable of supplying five lamps only, so that with all these dynamos there are none to spare in case of a breakdown. Electric lighting is scarcely one of those things which they have learnt to do better in France up to the present time.

A NEW SOURCE OF CARBON.—It is stated that an excellent carbon for electrical purposes can be obtained from sea-weeds. After thorough washing in hot water the material is dried and is then carbonised in closed retorts in the usual manner. The resulting product is then treated with dilute acid and dried. It is then said to be a perfectly pure form of carbon in soft masses or lumps, which may easily be crushed between the fingers, and after being ground makes an excellent raw material for the various purposes for which carbon is applied.

NEW RAILWAY ALARM.—The engineers of the French Western Railway are trying a new arrangement for communication between passengers and guard. It consists of pushes in the carriage compartments, wires along both sides of the carriages, and a bell and dial in the guard's van. The dial enables the guard to see from what compartment a signal proceeds, while switching off the wires on the near side of the carriages, on the train approaching a station, permits of his also being warned of any passenger attempting to alight or change compartments on the off-side.

DOCKYARD LIGHTING.—The *Broad Arrow* says:—"Times have advanced so fast that our Admiralty scarcely are able to keep pace with them. It is, however, to be hoped they will shortly turn their attention to the lighting our dockyards by electricity, and so increase their efficiency, which can be easily done at a small cost. The necessary steam-power is always available. The great advantage that would naturally accrue at night when, as is often the case, it may be necessary to work over hours, would be simply invaluable." We have reason to believe that this matter is now receiving attention at the Admiralty.

Digitized by Google

THE EASTERN TELEGRAPH COMPANY.—This company announce the payment, on the 14th instant, of interest at the rate of 3s. per share on the preference shares, less income-tax, for the quarter ending 31st December, 1886, and on the same day an interim dividend will be paid of 2s. 6d. per share in respect of profits for the quarter ended 30th September, 1886, on the ordinary shares of the company, free of income-tax. The register of transfers will be closed from the 7th to the 14th inst., both days inclusive.—The traffic receipts for December, 1886, amounted to £52,823, and to £53,179 in the corresponding period of 1885.

MILL LIGHTING.—We are glad to note the steady extension of electric lighting among the mill owners in the Leeds district. One of the latest installations of this character has been carried out by Mr. Wilson Hartnell in Messrs. W. and J. Bairstow's mills at Skipton, in extension of plant supplied four years ago. The new plant consists of one of Hartnell's compound-wound dynamos, supplying fifty-eight 16 candle-power Edison-Swan lamps, with movable fittings for examining the machines. The dynamo is driven by a 4 horse-power nominal vertical engine, fitted with Hartnell's automatic governors, the power being transmitted by belting.

AVELLINO, ITALY.—We learn from *Industries* that a contract for the electric lighting of Avellino has just been concluded between the municipality of that town and Messrs. Taddei, electrical engineers, of Turin. The installation will consist of 250 incandescent Cruto lamps, viz, forty of 32 candle-power, thirty of 24 candle-power, eighty of 16 candle-power, and 100 of 10 candle-power each. The Piazza della Libertà will be lighted by arc lamps of 250 candle-power. The current will be furnished by Thury dynamos, driven by a compound condensing engine of 150 horse-power. This engine and the two boilers will be supplied by Messrs. Tosi, of Legnano.

THE COWLES PROCESS.—The *Engineering* and *Mining Journal* of New York says that the success of the Cowles electric smelting process for the reduction of aluminium appears to have passed far beyond the experimental stage since the starting of the great dynamo. The working of this machine has proved so satisfactory that two additional dynamos of the same force have been contracted for, the present capacity of the works being unequal to the demand for their product. The use of aluminium alloys for guns is attracting a good deal of attention, and every process that tends to the cheaper production of aluminium is of the greatest interest and importance.

THE "ACHESON" DUPLEX WIRE.—Preparations are being made in the Pittsburgh factories of Mr. G. Westinghouse, jun., for the manufacture of a new type of insulated cable, intended primarily for telephonic purposes. The cable consists of a central wire, separately insulated, and surrounded by a copper tube ·006in. in thickness, made of electro-deposited metal, and insulated over all with cotton, treated with japanned paint. It is stated that this cable will not cost more than a cable of two separately insulated wires of the usual type. If this last statement is well founded, there can be no doubt that the "Acheson" cable will find a very extensive employment for underground telephonic work.

ATMOSPHERIC ELECTRICITY.—At a recent meeting of the Berlin Electro-Technical Society, Major Buchholtz, after describing some experiments which he has undertaken for the examination of the electrical condition of the atmosphere by means of a captive balloon, referred to a new observation of Dr. Vettin, by which he proposes to account for the fleecy rounded shapes assumed by cirrus clouds. According to the Doctor, if a mouthful of cigar smoke be gently blown along the surface of a table, and a charged electrophorus be brought near, the smoke will assume just this aspect. It is therefore suggested that the presence of such clouds denotes a highly electrical condition in the upper regions of the atmosphere.

DIRECT SPANISH TELEGRAPH COMPANY.—The reduction of capital having been sanctioned by the High Court of Justice, in the terms of the resolutions passed at the meetings of the 30th September and 19th October last, it will take effect from the present date (December 31st), and shareholders are requested to forward their certificates of shares to the manager, in exchange for which new certificates of the same shares as reduced will be issued. Holders of preference shares will receive with their new certificates a cheque for £2. 10s. per share, less income-tax, making up the full dividend payable upon their holdings in preference shares to December 31st, 1886.—The estimated traffic receipts of this company for the month of December were £1,767, against £1,764 in the corresponding period of last year.

ARC OR INCANDESCENT, IN 1834?—Arago, in his "Elogy of Alexander Volta," of which a translation appears in the *Edinburgh Philosophical Journal*, January, 1834, has the following passage:—"Pieces of charcoal fitted to the two extremities of the same wire, kindle as soon as they touch each other. The light they diffuse is so pure, sparkling, and remarkable for its whiteness, that we should not surpass the limits of truth by calling it the solar light. The charcoal attached to the two wires of the pile become, in fact, incandescent in a perfect vacuum. Nothing therefore can be incorporated in their substance, and nothing appears to emanate from them. At the close of an experiment, however long continued, the pieces of charcoal are found to be the same in nature *and in weight* as before it began."

ANOTHER ELECTRIC LOW WATER ALARM.—An automatic electric low water alarm for steam boilers of a particularly ingenious character has recently been introduced in America. The ordinary glass level tube contains a cork floating upon its surface, and this is all the apparatus which is placed in connection with the boiler itself. At the level at which the alarm is to be sounded a lamp is placed upon one side of the tube, and upon the other side a selenium cell is placed in circuit with a battery and an electric bell. The rays from the lamp are concentrated by a lens, but when the water is at its proper level the light is intercepted by means of the cork float. The resistance of the selenium cell is then so high that the current is unable to ring the bell. If, however, the water level sinks so as to allow the light to fall upon the selenium, the resistance decreases and the alarm is sounded.

LECTURES ON THE STEAM ENGINE INDICATOR.—The "special" lectures at the Finsbury Technical College for the present term will be delivered by Prof. Perry, F.R.S., who takes as his subject the "Steam Engine Indicator Diagram." We understand that Prof. Perry has had a number of pieces of new apparatus specially prepared to illustrate these lectures. The subject, though in one sense a purely mechanical one, is of great interest to electrical engineers, inasmuch as the correct measurement of the power supplied to a dynamo is frequently a matter of some moment. A course of laboratory instruction has been arranged in connection with Prof. Perry's lectures, thus carrying out the principle which pervades the Finsbury courses of instruction. Prof. Perry also proposes to continue the voluntary class for instruction in the simpler applications of the differential and integral calculus. It is not generally known that this class is open, free of additional charge, to all evening students of the classes at Finsbury.

Telegraphic Communication with the Continent.—With regard to the statement that the recent breakdown of the British lines communicating with the Continent was due to the monopoly of a private company, Mr. Clare, secretary of the Submarine Telegraph Company—the company referred to—points out in a letter to *The Times* that several of the cables connecting this country with the Continent are the property, not of English, but of Continental companies; and that the English Government is itself the owner of two cables to Holland, and one to Germany. Mr. Clare adds that "The land lines which have broken down from London to the Coast in connection with all the cables laid down across the Channel to the Continent belong exclusively to Her Majesty's Government, who is solely responsible for their proper maintenance, and who alone can erect land lines in this country. None of the companies have the power to erect land lines in connection with their cables."

The French Academy Prizes.—The subject proposed by the Academy last year in competition for the "Grand Prize de Science Mathematiques," which consists of a gold medal of the value of 3,000fr., was the following:—To perfect in some important point the theory of the application of electricity to the transmission of energy. The committee of adjudication consisted of MM. Levy, Becquerel, Bertrand, Fizeau, and Cornu. They have reported as follows:—Only one memoir has been sent in upon the subject; this memoir, in spite of several points of interest, and a judicious discussion of the problem, has not seemed to the committee to sufficiently respond to the programme proposed by the Academy. Some experiments now in course of execution would seem to put the author in a position to obtain a more complete confirmation of his ideas. The problem of the electric transmission of power is now being made the subjeet of profound study from many sides. Under these circumstances the committee have thought it best to reserve their award for the present, and, without prejudice to the author of the paper already received, to allow the competition to stand open until June 1st, 1887.

On the Specific Induction of Magnets in Magnetic Fields of Different Intensity.—In the *Centralblatt für Elecktrotechnik*, Dr. Hilmar Sack has a paper to the following effect:—The specific induction of a magnet is the increase or decrease of the magnetic moment of the unit of mass by the unit of magnetising or demagnetising force respectively. Dr. Sack's experiments were conducted on a hardened steel bar, which had been strongly magnetised and subsequently treated for a long time in boiling water or steam, by placing it in a solenoidal coil, through which could be passed a current of given intensity either positive or negative in sign. The results are that, for magnetic fields of an intensity not exceeding six times that of the earth's horizontal component, the value for increasing and decreasing force is the same; this also holds good for fields up to seventeen times the earth's horizontal component, if the bar be first subjected to a series of reversals of the current, for the first application of the current gives a larger value than subsequent ones. No permanent alteration in the moment of the bar can be positively detected until the magnetic field is twenty times as strong as the earth's horizontal component.—*Journal* Inst. Civ. Eng.

Method of Indicating the Potential of Incandescent Circuits.—In central station lighting when worked direct from parallel distribution, whether with two or three wires, it is essential to have some means of knowing the difference of potential in various distant parts of the circuit. For this purpose it is customary to carry "pressure wires" from the terminals of the various feeders back to the machine room, and hitherto these wires have been connected with a voltmeter, which indicates, or should indicate, the actual differenco of potential in volts. As a matter of fact, however, unless much trouble is undertaken in the frequent and careful calibration of the instruments, it is found in practice that the error often attains a magnitude leading to serious differences in the potential actually maintained at various points in the circuit. In order to overcome this difficulty, and at the same time to avoid the necessity for re-calibration, Mr. John Howell, of the Edison Company of New York, has introduced a system by means of which only one standard instrument has to be calibrated in volts. This standard instrument is connected with the terminals of any one feeder; the "pressure wires" from all other feeders are connected with simple differential galvanometers, and the second circuit in each of these galvanometers is connected in parallel with the standard instrument. The needles then show at a glance whether the difference of potential at the terminals of each feeder is greater or less than that at the terminals of the standard. The idea is both simple and ingenious, and will undoubtedly receive a wide application.

Electrical Conductivity of Solid Substances at a High Pressure—In the *Ann. Phys. Chem.* a paper "On the Electrical Conductivity of Solid Substances at High Pressures" is contributed by L. Graetz. Hitherto our knowledge of the conductivity of electrolytes is derived for the most part from results obtained with the substances in the dissolved and not in the fused condition. Although it is *à priori* to be expected that the law governing these phenomena in the case of a homogeneous media would be of a simpler character than those in the case of heterogeneous media, namely, a solution of salt in water, yet the result of experience is the reverse. The only generalisation at present deduced is that solid substances are not conductors at low temperatures, but their conductivity commences at temperatures far below the melting point, and increases with the temperature. If, then, this increase of conductivity is due to an increase of molecular mobility and of the number of molecular impacts, increase of pressure without alteration of temperature should be effective to a like degree. In the paper this point is examined by means of a compression apparatus, capable of giving a pressure of upwards of 4,000 atmospheres. The results are given for the halogen compounds of lead and silver, and for sodium nitrate. The substances examined are divisible into two classes, in the one of which, with application of maximum pressure, the resistance rapidly decreases to a constant point, and in the other this minimum resistance is, under the same condition, only attained after several hours. To the former class belong the halogen compounds of silver, to the latter those of lead and sodium nitrate. In the paper full details are given of the apparatus used, and of the methods of experiments; the results are tabulated.—*Journal* of the Chemical Society.

M. de Meritens' Process for Rendering Iron Inoxydisable.—M. de Meritens, in continuing his experiments upon the protection of iron, has obtained some further results, which seem likely to be of practical importance. The method of protecting an iron or steel surface by the electrolytic formation of a coating of the black magnetic oxide has already been taken up in France as a commercial process. Experiments in this direction have also been undertaken in the French arsenals, and are understood to have led to satisfactory results. The details of the process, which is very simple and inexpensive, will be found in *The Electrician* of 23rd July, 1886. M. de Meritens describes his later researches in a note presented to the French Academy, as follows:—"When we

submit a piece of iron to the action of the current in a bath of cold water the formation of magnetic oxide does not immediately take place. The surface of the metal is in the first place coated with a layer of the protoxide of iron. This is a body of which little is known at present; it has not been completely studied by any chemist. Berzelius undertook a prolonged investigation of the substance, but he has never completed the work. The protoxide is the least stable of the oxides of iron. If it is produced by precipitation from a salt of iron, it is immediately converted into the sesqui-oxide. A similar conversion into the higher oxide takes place when the protoxide formed upon the surface of the metal by electrolysis is exposed to the air, or if the electrode is allowed to remain in the bath after the cessation of the current. If, however, the sheet of iron coated with the protoxide is immediately transferred to a bath containing a solution of a suitable salt of some other metal, such as copper, silver, gold, or aluminum, a perfectly adherent layer of this metal is immediately formed upon the iron. It is probable that the action is due to a partial reduction of the protoxide by hydrogen, and the formation of an actual alloy between the two metals, both of which are at the moment in the nascent condition." M. de Meritens exhibited specimens of iron coated by this process with the several metals named above.

Open and Closed and Magnetic Circuits.—Professor Mascart has recently undertaken some experiments in order to compare the coefficient of magnetisation in closed rings with that for cylinders of different lengths. Hitherto the coefficient in the former case has always been found to be higher than in the latter. The question arises (according to Prof. Mascart) whether one of the methods is liable to error; whether in rings, for instance, a special phenomenon exaggerates the effects of induction. In order to determine this question a series of electro-magnets were prepared, all of the same iron wire; some of these were closed rings, and others in the form of cylindrical rods in which the ratio of the length to the diameter varied between very wide limits. It was found that for the particular quality of iron employed, when the ratio of the length to the diameter varied from 40 to 500 or 600, the maximum value of the co-efficients varied from 25 to 190 or 40 to 220, while the corresponding magnetic fields diminished from 20 to 25 C.-G.-S. units to 3; the same wires employed in the form of rings gave similar values. Interpreting this result in the light of the views of magnetic resistance which now find acceptance upon this side the Channel, it is easy to understand (what, however, was well known long before Prof. Mascart's late experiments) that the coefficient of magnetisation is greater in a long bar than in a short one, because of the greater area afforded for air leakage, together with the more rapid ratio of decrease in the number of lines with regard to the length of the bar. The total magnetic resistance of the circuit thus diminishes as the length is increased. The fact that for very long bars the coefficient was found to be the same as for rings, appears to us simply to denote that the iron had in each case arrived at the straight part of the curve of saturation. Upon this point, however, the data supplied are not sufficient to enable a definite opinion to be formed. As regards short cylinders it was found that as the ratio of the length to the diameter diminished the mean coefficient of longitudinal magnetisation diminished very rapidly, and eventually became equivalent to the transverse. The coefficients were more nearly equal when soft steel was used, and much more so with tempered steel.

The Collapse of Overhead Wires.—The daily papers, as might have been expected, are publishing numerous letters from the public on the overhead wire question. The following letter from Mr. H. W. Tyler, which appeared in *The Times*, may be taken as a specimen:—"Sir: Anyone who walks about London to-day will see, if he diverts his attention from the slush in the streets, hundreds and hundreds of overhead wires which have succumbed, like the cedars and other trees in our gardens, from the effects of last night's snowfall. Both in the City and at the West End great has been the destruction. Broken and bent telegraph posts on the roofs, wires rolled up and put away in corners, with ends hanging or tied round railings or lamp-posts, are visible in all directions. Telegraph and telephone communication has been materially interrupted, in the metropolis as well as throughout the country. The expense of the reinstatement of these posts and wires will necessarily be considerable; and there will be the same liability to destruction when four inches of snow again falls suddenly. But the most serious part of the question is the danger to life and limb which is constantly incurred by the suspension of this constantly increasing network of wires over the heads of the hundreds of thousands of people who are constantly using the streets. There is, no doubt, a certain amount of temptation to allow, for the sake of cheapness, convenience, and profit, this danger to be continued, and it will be an uphill battle to fight before the happy consummation can be arrived at of burying these wires underground. But it will have to be done sooner or later, in this as in other cities, by the Post Office, the telegraph companies, and the telephone companies, as it has already been done to a great extent in some cities and by the Post Office here. The report of the recent Parliamentary Committee was not considered a success, even by some of those who were concerned in framing it. And, indeed, it is sufficiently obvious to all who are acquainted with the strength and durability of materials, with the tendency of wire to fly when stretched tightly and fractured, and with the weakness of the human frame to resist flagellation so administered, that serious and increasing dangers are the result of the present system. Unless, by pegging away, we can sooner cause the remedy to be adopted, we must wait till serious accidents and loss of life in high quarters have been occasioned, and then we shall, no doubt, be relieved from the birdcage existence to which we have now, for many years, been more and more trained."

The Repairs to the Telegraph System.—The work of repairing the damage done to the telegraphs by the recent snowstorm—the most disastrous storm which has ever occurred to the English telegraph system—is going on with great vigour, and the only important town which now remains isolated from the telegraph system is Portsmouth. North of that point communication has nearly everywhere been restored. The wires of the Submarine Cable Company have likewise been very much improved, and by the erection of lines to Beachy Head and Lowestoft the services with France, Holland, Germany, and Belgium have been reopened. Messages which cannot be sent to the Continent direct by either of these routes are forwarded by train to Dover, and telegraphed thence by the cables which remain intact. Among the companies, the Great Western is by far the heaviest sufferer. Over the greater part of this company's system the destruction of the wires has been complete, and nothing short of a permanent restoration is possible; while on other railways temporary wires have been erected. The Great Western Company have in these circumstances been granted the services of 100 Royal Engineers. As the railway companies are responsible for the efficient maintenance of the Government wires which are carried along their lines, the storm will involve some of them in considerable loss.

Digitized by Google

When postal telegraph wires are erected on railways in England the Government supply the material, and the railway companies construct at the expense of the department, and afterwards, on an annual remuneration at the rate of 20s. per wire per mile, keep the service in efficient working condition. In ordinary times this payment yields profit to the companies, but it will be insufficient in several instances for the restoration which has now become necessary. To indicate the extraordinary pressure which was brought to bear on the telegraph wires during the late storm, it may be stated that on the main roads running to the south-west of England, a large number of A poles were not snapped, but literally dragged out of the earth and hurled with the wires over the edge into the fields. These A poles are the strongest which can be employed. The two sloping posts are sunk into the ground, and are firmly tied with wire. On no previous occasion have these poles been found unable to withstand the strain placed upon them. Although there has been a great demand for new poles, the stock in hand is sufficient for all requirements. Indeed, the department is so well provided for as to be able to offer to send a number of poles to the Great Western Railway, but that company, being equally fortunate in its reserve, was not called upon to accept the aid thus suggested.

The Employment of Spiral Springs for Measuring-Instruments.—In a paper by Prof. W. Kohlrausch, in the *Electrotechnische Zeitschrift*, on the employment of spiral springs for measuring-instruments and the accuracy of galvanometers constructed therewith, the causes which are likely to affect the constancy of spiral springs are mentioned in detail by the author, with an account of experiments bearing on each point, in order to afford some idea of the reliance that can be placed on the indications of instruments into the construction of which they enter. The effect of age, judging by observations on a brass spring extending over a period of seven years, may be completely neglected. Continuous and prolonged deformation produces a small amount of permanent set, so that the spring when released does not return to the original position, but does not actually alter the indications of the instrument if the readings are taken from the new zero thus found; steel is in this case less affected than German silver. Oft-repeated, but intermittent deformation—as exhibited by a spring of 90 convolutions and 2½in. long being stretched so as to change from a length of 3½in. to 9in., two hundred times per minute for four hundred minutes—introduced no appreciable alteration in its subsequent indications. An increase of temperature of 18° Fahrenheit raised the indications of a Siemens torsion galvanometer about $\frac{1}{10}$ per cent., so that the reduction in the elasticity of the spring is apparently almost equal to the decrease in the moment of the magnet, which would be, under these conditions, about 0·4 per cent. Further experiments on loaded springs confirmed this conclusion, and showed that steel was again to be preferred to German silver. By combining the results given above, the utmost limit of error introduced by the use of spiral springs cannot exceed 0·5 per cent. If, however, as is the case in the Siemens tension-galvanometer, the current passes through the spiral spring, care must be taken that the heating from the passage of the current is not excessive. The author found an alteration of 1·4 per cent. in the indication of such an instrument after 30 minutes continuous test, with a difference of potential of 100 volts between the terminals. If such instruments be calibrated at intervals to correct the decrease in the moment of the magnet, an accuracy within about 0·1 per cent. can be relied on, With the Siemens dynamometer for intense currents, the limit of error, owing to the friction at the mercury contacts, is about 1 per cent. Another form of instrument, the spring-galvanometer of F. Kohlrausch, is also reliable within 1 per cent., and is perfectly aperiodic with frictionless damping. Owing, however, to the employment of an iron core, the readings of currents taken in ascending and descending order of magnitudes will vary to some considerable percentage from the effect of residual magnetism, which exists in even the best soft iron, if this error be not eliminated by mechanically bringing the core past the position it would take up under the action of the current, and then leaving it free to return to that position.—*Journal* Inst. Civ. Eng.

New Application of Electrolysis to the Desilverisation of Lead.—The application of electrolysis to metallurgy is progressing with great rapidity, and we have no doubt that all dynamo manufacturers will before long find it necessary to design special plant for this purpose. According to the *Engineering and Mining Journal* a new process has been recently brought out in Germany for treating the argentiferous zinc crusts and skimmings electrolytically. "Heretofore, this alloy has most generally been worked further by distilling off the greater portion of the zinc it contains and obtaining a residual rich silver lead, sufficiently free from zinc to be submitted to cupellation. This distillation of a material consisting of over 80 per cent. of lead is a very troublesome operation, and though it is carried on with satisfactory results, still it remains the most difficult and expensive operation in the otherwise excellent process of desilverisation by zinc. The new process under consideration appears to offer many advantages that promise to make its introduction and adoption soon general. It is as follows: The zinciferous silver lead is first reduced to wheat size, and is then placed in a wooden vat, the bottom of which is covered with sheet lead. The vat is filled with an electrolyte liquor of sulphate of zinc, and a cathode plate of metallic zinc is suspended in the liquor at a suitable distance from the bed of alloy. This cathode is connected with the negative pole of a dynamo, the positive pole of which is connected with the lead bottom of the vat on which the alloy rests. By the action of the current, zinc is deposited on the cathode, and an equivalent portion of the zinc in the alloy is dissolved out. If this could be carried on till all the zinc was removed the process would be perfect, as all the zinc would be regained for use over again, and the residual silver-lead would be ready for cupellation. It is found that the amount that can be so dissolved out depends entirely on the surface exposed, the solution acting very slowly as the depths of the pores increase. When the electrolytic action becomes very weak and almost ceases, the bed of material is taken out, washed, and placed on the hearth of a liquating furnace. The exterior of the granules, being now entirely free from zinc, the silver lead is easily liquated down to the point where the unattacked alloy once more appears on the surface. The lead obtained from this operation is, of course, ready for cupellation. The residuum is once more granulated and replaced with fresh material in the vats, and subjected to electrolysis, until the lead again increases so far in proportion to the zinc as to make it profitable to again liquate it. In this manner, the two processes alternate, until the separation is complete. While at first sight this constant rehandling of the material appears to offer serious objections, still in practice it has proved much cheaper, both as to fuel used and in the increased saving of metallic zinc, than the distillation processes heretofore in use. By reducing the size of the grains as far as compatible with the circulation of the sulphate liquors through the mass, the number of times the alternating operations take place may possibly be reduced to two or at furthest three, and doubtless before long the strength or even composition of the bath will be so regulated that the whole process of dezincifying may be completed in one operation."

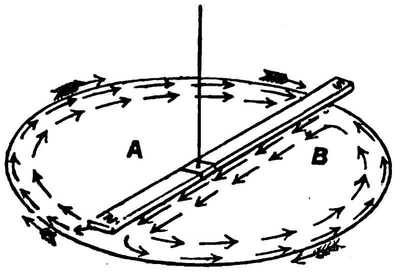
ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 165.)

It is clear that in Aragos's experiment the magnet can never turn at the same rate as the copper disc, for it is only when the disc is moving relative to the magnet that the lines of force are cut by the copper, and any current is generated in the disc. In the figure the winged arrows show the direction in



which the disc is rotating, and the unfledged arrows indicate in a general way the distribution of currents in the disc. The circuit marked A will attract the north pole and repel the south pole of the magnet, while the circuit marked B will act in the opposite manner, and hence the magnet will be compelled to follow the disc in its rotation. The universal tendency of induced currents is to destroy relative motion. Of course the magnet exerts upon the disc forces equal and opposite to those exerted by the disc on the magnet, thus tending to retard the disc. This means resistance to the action of the driving agent. If the couple exerted between the magnet and disc be determined, the product of this couple and the angular velocity of the magnet gives the rate at which work is done in maintaining the motion of the magnet. The product of the couple and the angular velocity of the disc gives the rate at which the agent has to work in driving the disc against the action of the magnet. The difference between these products—that is, the product of the couple and the angular velocity of the disc relative to the magnet—gives the rate at which work is done by the driving agent in maintaining the induced current in the disc.

Faraday conceived that a conducting circuit placed in a magnetic field is thrown into a peculiar state, which he called the *electrotonic* state, and that it is upon the changes of this state that induced currents depend. He frequently reverted to this idea. Faraday's electrotonic state consists simply of the number of magnetic lines of force which pass through the circuit (in the positive direction). As we have seen, the induced electromotive force is equal to the rate of diminution of these lines of force. If the circuit be a coil consisting of several turns of wire, we must add together separately the numbers of lines of force passing through each turn of the wire.

Bell's telephone, when employed as a transmitter, affords a simple illustration of the laws of induced currents. It consists essentially of a bar magnet, having a small coil of wire wound round it near one pole. In front of this pole is placed a thin iron diaphragm, which responds to the vibrations of sound. The terminals of the coil are connected with the circuit. When the diaphragm, in its vibrations, approaches the pole of the magnet, the lines of force pass more directly from the end of the magnet to the diaphragm, and consequently nearly all of them go through every turn of wire in the coil; but when the diaphragm is at a greater distance from the end of the magnet, the lines of force diverge more from the sides of the bar magnet, and some of the lines of force do not pass through every turn of the wire. Hence as the diaphragm moves there must be a current induced in the coil. This current passes along the line and around the coil of the receiving telephone, increasing or diminishing the magnetisation of the magnet according to the direction of the current, and thus causing the diaphragm of the receiving telephone to vibrate in sympathy with that of the transmitter.

When a current is started in a coil the current in each turn of wire causes lines of force to pass through that turn and through every other turn of wire in the coil. As the current increases the number of these lines of force passing through each turn of wire will also increase, and this must cause an induced electromotive force in every turn of wire, which will be in the negative direction with respect to the lines of force—that is, in the direction opposite to the current in the coil. These induced electromotive forces in the several turns will together constitute an electromotive force which opposes the battery, and the current flowing in the coil will be determined by taking the difference between the E.M.F. of the battery and the induced E.M.F., and dividing this difference by the resistance of the circuit. Of course the induced electromotive force must always be less than that of the battery, and so much less that the current is increasing, for otherwise the cause of the induced electromotive force, viz., the increase of the current, would cease. The result of this action, which is called *self-induction*, is to cause the current to increase steadily instead of suddenly, and to take some time before it attains its final value, as determined by the E M.F. of the battery and the resistance of the circuit.

Similarly, when the current dimishes the number of lines of force passing through each turn of wire will diminish, and there will be an electromotive force generated in the same direction as the current and tending to prevent its decrease, the measure of this induced electromotive force being equal to the rate of diminution of the number of lines of force passing through the circuit. Hence, it is clearly impossible for a current in a coil to cease suddenly, for this would entail an infinite electromotive force in the direction of the current. By breaking the continuity of the coil and rapidly separating the ends of the wire an enormous resistance can be very quickly thrown into the circuit and the current very quickly stopped, but this causes a very great electromotive force to be induced, which compels a current to pass for some time across the gap, though the current must, of course, diminish very rapidly, as otherwise there would be no induction. The presence of an iron core in the coil very much increases the self-induction. The effect of self-induction in the phenomena of electric currents is, in some respects, similar to that of mass in ordinary dynamics. It requires a finite electromotive force to act for a finite time to produce a finite change in the strength of a current. But it should be noticed that the self-induction does not depend simply on the strength of the current and length of the conductor, but also on the configuration of the conductor. A coil of wire has a very much greater self-induction than a straight wire of the same length, and the more closely the several turns of wire are brought together the greater is the self-induction.

Again, an amount of work proportional to the square of the strength of the current has to be expended in starting the current, and this amount of work must be performed by the current before it can cease. In this respect, too, the self-induction of a conductor resembles *mass*, the energy expended in starting the current and possessed by it, or by some invisible mechanism connected with it, being analogous to the kinetic energy developed in a moving mechanical system. It is therefore impossible to instantaneously generate a finite current in a conductor, just as it is impossible to instantaneously generate a finite velocity in a portion of matter, because no agent can work at an infinite rate or exert an infinite force; and in the same way it is impossible to instantaneously destroy a finite current. But the rate at which a given electromotive force can generate a current depends on the form as well as the length of the conductor, for the self-induction of a coil is very much greater than that of the same wire when straight; and this suggests that the energy is to be sought for, not so much in the conductor itself in which the current is flowing, as in some mechanism external to the conductor and intimately related to it—a mechanism, in fact, by which the several parts of the wire are connected together and upon which every element of the conductor conveying the current acts. Clerk Maxwell identified this mechanism with the luminiferous ether, and the motion to which the energy of the current is due with a rotatory motion of the particles, or "cells," of the ether. The stresses introduced in the elastic substance of these cells by the rotatory motion he identified with magnetic force.

Digitized by Google

According to this system the energy of an electric current is to be looked for not, in the conductor in which it flows, but in the whole of the surrounding space to which its magnetic influence can extend.

Faraday investigated the phenomena of self-induction, his attention having been called to the subject by Mr. William Jenkin, who noticed that when he broke the circuit of his electro magnet, holding the extremities of the wire in his hands, he received a sharp shock, although the battery itself was unable to send any appreciable current through his body. The separation of the ends of the wire introduced a resistance of several thousand ohms into the circuit, and this, of course, produced a great diminution of the current. The diminution of the current caused an electromotive force to be induced in the coils of the magnet tending to sustain the current, and this E.M.F. was many times greater than that of the battery. It was, therefore, capable of sending a current through the body of the operator much greater than that which the battery alone could produce, and this instantaneously produced a shock. The induction current, though much greater than that which the battery could send through the circuit with its increased resistance, was, of course, very soon much less than that which the battery had sent through the magnet alone, for it was not till the current began to diminish that the induced electromotive force came into existence.

Induction currents are generally of very short duration and vary very much while they last. They, therefore, cannot usually be measured as currents, though it is possible to measure the total amount of electricity which passes during the whole time that the current lasts—that is, to measure the amount of the electric *discharge*. In this respect induction currents resemble those mechanical forces, generally known as impulsive forces, which cannot be measured as forces by the *rate* at which they generate momentum, though their impulses can be measured—that is, the whole amount of momentum which they generate while they last.

Def.—The coefficient of induction of one coil upon another is the electromotive force which appears in the second coil when a current is being increased at unit rate in the first.

Thus, if a unit current were generated in the first coil in one second, starting from nothing and increasing uniformly, the electromotive force in the second coil, which would be constant during the second, would represent the coefficient of induction.

Hence, the coefficient of induction of one coil on a second is equal to the number of lines of force which pass through the second coil when a unit current flows in the first.

It can be shown by calculation in simple cases, and experimentally in all cases, that the coefficient of induction of one coil upon another is equal to that of the second on the first. Hence, this coefficient is called the *coefficient of mutual induction of the two coils.*

Def.—The coefficient of self-induction of a coil is the number of lines of force which pass through the coil when a unit current is flowing in the circuit.

(To be continued.)

INCANDESCENT LAMP MANUFACTURE.—IV.

BY J. SWINBURNE.

Amyloid Carbon. (*Continued.*)

Sulphuric acid may also be used for acting on paper, so as to make material out of which flat carbons may be cut. Parchment paper may be bought ready made, and it would scarcely be worth any lamp maker's while to make it himself. It is generally used for covering preserve jars, and for book binding; and the quality used for these purposes is thin. If it is wanted thick it can be readily obtained wholesale in the City.

Having obtained the parchment paper, the next thing is to cut it up into slips which, when carbonised, shall all have the same surface when the length is the same.

It will be convenient now to describe the processes available for all carbons cut from sheets, not only of sulphuric acid parchment paper, but from amyloid made by any method, or from sheets of any material that can be cut.

Lamps have practically always carbon loops, and if these loops are flat strips of carbon they may either be cut in straight slips, and these slips may then be bent over, so as to make a loop like that of a sugar tongs; or the loop may be cut flat out of the material, so that it does not need to be bent over, thus making a flat loop like that of a horseshoe.

Cutting these strips is, as has already been stated, a very difficult matter. The best way of cutting the sugar-tongs loops is to fasten a sheet of the material round a mandrel, and then screw-cut it with a very sharp tool. Parchment paper unfortunately takes the edge off a steel tool very quickly. The same thing may be observed in working up vulcanised fibre for insulating purposes. The sheet of parchment paper should be overlapped, so that the result is a long tape of parchment paper of uniform breadth, with joints every here and there. The mandrel should be of large diameter, so that there is a fair length between each joint, otherwise there will be difficulties in carbonising. To carbonise such strips they are wound on frames, and if the length from joint to joint in the strip is not an exact multiple of the distance round the frame, the joints will come in the wrong places. It is best, therefore, to have as few joints as possible. The carbonising frames should be filled as soon as the strip is cut, as otherwise the strip is apt to curl about and twist, as it absorbs or gives out moisture unevenly. Of course the carbons may all be cut separately, a sheet of parchment being used which is just long enough to allow a reasonable margin. Instead of pasting the overlapping material so as to screw-cut it into a continuous, or rather, a jointed strip, the overlapping part may be on a flattened part of the mandrel. This gives a sheet with a number of parallel cuts, which do not reach the sides; and the sheet can be bent over a carbonising block. In practice, however, all the little flat loops do not lie nicely, but one gets under the other on the carbonising block, and the outer ones get stretched or broken. The same sort of sheets may be got by mounting a sheet of the material on lead on the table of a slotting machine. The slotting head has a tool like a broad plane iron, and the lead is fed under it. When it is remembered that the strips must be about four inches long, and only a fiftieth of an inch broad, the difficulty of cutting a number all alike may be realised. A difference of half a mil., or one two-thousandth of an inch, will affect the resulting lamp. The writer has not had much experience in cutting carbons for sugar-tongs loops.

Horseshoe loops are cut by means of punches. Weston punches or cuts a long wavy carbon out of a flat sheet of what he calls *tamidine.* This wavy strip has broader ends for mounting, and perhaps to secure uniform length, with the object of thus getting uniform surface. The punch is probably made in two pieces fastened together, and is probably arranged like those used by fancy stationery manufacturers. The wavy strips are bent over, keeping the flat ends in the same plane, thus getting a wavy loop. The strip turns through a right angle in each leg, so that the top of the loop bends as a sugar-tongs loop, though the rest of the strip is as in a horseshoe loop. The great drawback to such a form as this is the difficulty in testing it. The light emitted in any direction has no definite relation to the whole of the light given by the lamp. In testing a flat carbon lamp the ratio of the measured light to the whole spherical emission can be got when the dimensions of the carbon are known; but in Weston's lamps this cannot be done. The plan of leaving thickened ends on is also bad. In the first place, if the surface per inch of carbon does not come quite right the error in the lamp cannot be corrected by using a slightly shorter or longer carbon. In the second place, the thickened ends always contain occluded gases, which can only be got out with difficulty on the pumps.

Maxim used M-shaped paper carbons, which were beautifully stamped. They were probably made with a kind of stationers' punch. The lamps were about 30 candle-power at ·25 candle-power per watt, and the carbons were broad; otherwise there would have been difficulty in making the punches.

The best way of punching very long and narrow carbons is the double method. A blank is first punched out. This blank is then placed in another press, and a similar blank very

Digitized by Google

slightly smaller is removed from the centre. A long narrow carbon is thus left. A broad cross-piece is left at the end so as to hold the finished blank, and to keep the ends of the carbon in the right position during carbonisation. Tools for such purposes as these must be very carefully and accurately made. The presses have to work very accurately. The writer used fly presses, such as used for brass work, but very carefully made. The die—that is to say, the part with the hole—is made of hardened steel, and the punch is soft. The punch is made just a shade too large, and is then mounted in the press and driven into the hole. The die takes off a minute cut all round, and leaves the punch an exact fit. The punch will then cut the finest tissue paper with ease. It soon loses its edge. The edge is therefore turned out a little with a burnisher, and the punch again driven into the die. Soon the burnisher is of no avail, and a hammer and round nosed punch must be used. If the die loses its edge it is sharpened by means of a small oilstone. The second punch and die are similar, except that they are smaller. The die has a brass guide piece to hold the blank exactly in the right position. The fly presses must have stops, so that the punches cannot be raised high; even with stops, a persevering girl will get her finger tip under the punch. In punching amyloid carbons two presses must be used, for the blanks curl about, and the least alteration of shape between the first and second punchings is fatal. It does not do, therefore, to punch a quantity of blanks one day, and then change the dies and punch the centres out of them next day.

Lane-Fox, as already mentioned, used vulcanised fibre as material to carbonise. Vulcanised fibre does not appear to be perfectly homogeneous. If a thick piece is carbonised it will be found to split up into flakes, showing that the material is made up of numbers of thin sheets stuck together by being partly gelatinised. Mr. FitzGerald has also patented zinc chloride carbons.

Parchmentising by means of zinc chloride is much more difficult than by sulphuric acid. No directions seem to have been published that will enable anyone to make carbons by zinc chloride solution. Mr. FitzGerald's solution does not give good results. If the writer's memory is not at fault, Mr. FitzGerald's is the Irish specification, which says the inventor takes a hot solution, which he prefers to use cold.

The best method of making thread carbons by zinc chloride is to use a strong solution. The ordinary stick chloride may be shaken up with water till a saturated solution is obtained. This may be diluted with about 10 volumes per cent. of water. Zinc chloride solution does not behave quite like sulphuric acid; for if sulphuric acid is too strong it acts on the cotton too quickly, and turns it into dextrin, but strong zinc chloride solution does not act on cotton. There appears to be one strength at which cotton is soluble in the cold, but it is very slowly acted upon. It is therefore better to use the solution stronger than this, and to pass the thread through it and then leave it on a tile exposed to the air. If the thread is watched it will be found to absorb moisture from the air and gradually to become transparent. After a time it will be so liquid as to begin to run. If the tile is now held under gently running water, the zinc chloride will be washed out, leaving an amyloid thread like that prepared by sulphuric acid. If the zinc chloride solution was too strong to start with, it will absorb too much water before the cotton is attacked, and the thread will be turned into an uneven flat strip. If the solution was too weak the cotton will not be acted upon at all.

Stick zinc chloride contains zinc oxide, formed when it was fused, and this may have some deleterious action. The oxide of zinc is soluble in the chloride. To obtain chloride free from oxide, granulated zinc is dissolved in dilute hydrochloric acid, excess of zinc being present. When the acid is quite used the dilute solution is filtered, and then concentrated by evaporation. The solution made this way is quite clear, while that made from the fused chloride looks chalky.

The writer finds the solution of zinc chloride in hydrochloric acid gives much better results. Zinc chloride dissolves freely in hydrochloric acid, with great evolution of heat. As the heat causes copious fuming, the chloride should be added a little at a time, till a saturated solution is obtained. This is then diluted to about 1·745, and the thread is drawn through, and then exposed to the air, as in the case of the aqueous solution of zinc chloride.

A solution of zinc chloride in equal volumes of hydrochloric acid and water acts very well also. In fact the aqueous solution of fused zinc chloride will be found very much the better of the addition of enough strong hydrochloric acid to clear it.

It is generally advisable to boil the cotton in a solution of borax before use in these amyloid processes, as that seems to remove traces of grease or resin, and to make the cotton more absorbent. Of course it is dried again.

Chloride of zinc does not destroy the fibre of the cotton so well as sulphuric acid. How far it is really necessary to destroy the fibre it is difficult to say. Thread still distinctly showing the twist of the cotton sometimes makes good lamps; but carbons made of such material writhe round when the lamp is lighted, and go back again when it is switched off. Zinc chloride allows a closer twisted thread to be used, as it has plenty of time to soak into the interstices before the fibres begin to swell and gelatinise.

Paper may be treated with zinc chloride solution. Loose textured blotting paper is good, but Swedish filter paper is better. A sheet is dipped, and allowed to soak thoroughly, and then laid on glass to gelatinise. When perfectly clear the sheet is washed thoroughly; it will float off the glass. It is not easy to dry these sheets so as to get them flat, as they get distorted during the washing and dry wrinkled. It is then impossible to stamp the blanks out. Vulcanised fibre can be got very thin, but it does not make good carbons. Probably it is not thoroughly devoid of fibre.

It is hardly necessary perhaps to caution anyone as to the use of hydrochloric acid solutions of zinc chloride. They give off great quantities of hydrochloric acid, which is exceedingly bad for the lungs.

The solution of zinc chloride acts more strongly when hot, but it also has a much greater tendency to convert the cellulose into dextrin. An aqueous solution of zinc chloride of sp. gr. 1·86 – 1·9 acts on cellulose at the temperature of boiling water; but a little extra heating will convert the jelly into a thin liquid. It is difficult also to get rid of the last traces of fibre.

THE PHYSICAL PROPERTIES OF MANGANESE STEEL.

At the last meeting of the Royal Dublin Society, on 15th December, Prof. Barrett, of the Royal College of Science, Dublin, read a paper on the above subject. Prof. Barrett pointed out that Mr. J. T. Bottomley had sent a brief note on the non-magnetic character of manganese steel to the Aberdeen meeting of the British Association, and had kindly furnished him with a specimen of this steel, and the name of the makers and patentees, Messrs. Hadfield and Co., of Sheffield. The steel contains 12½ per cent. of manganese. Through Messrs. Hadfield, Prof. Barrett had obtained wire drawn from manganese steel, a process that first presented great difficulties, but was ultimately accomplished with ease by heating the steel to whiteness, and quenching in cold water after every reduction through two sizes. Sudden cooling softens this steel; slow cooling hardens it. A No. 19 wire (diameter 0·98 millim.) was thus obtained of two kinds—hard and soft; the density was 7·708. The electric conductivity was found by Prof. Barrett to be very low. The No. 19 wire had a resistance of an ohm per metre, the specific resistance in C.-G.-S. units being 77,000 for 1 cubic centimetre; ordinary iron wire is only 9,800, and German silver 21,170; so that a use might be made of manganese steel for resistance coils in electric lighting.

The magnetic character of this steel was then carefully tested by Prof. Barrett. Mr. Bottomley found the intensity of magnetisation of this steel, after submitting it to the most powerful magnetising force, was 2·55 in C.-G.-S. units, or the magnetisation per gramme was 0·013 in C.-G.-S. Ordinary steel gives a number varying from 40 to 90, and even 100 C.-G.-S. units per gramme. So that if ordinary steel of average quality be 100,000, manganese steel is 20.

This represents the permanent magnetism. Prof. Barrett,

Digitized by Google

by different methods, has determined the susceptibility, that is, the induced magnetisation, in a uniform field. Compared with iron as 100,000, manganese steel was found to be 300. In fact, it is very wonderful to find no sensible attraction exerted on this steel by the most powerful magnetic field that could be obtained.

Hence, as Prof. Barrett suggested in his paper, its use for the bed plates of dynamos and the plating of iron vessels is obvious. Ships built of such steel would have no sensible deviation of the compass. As excellent castings can be obtained from this steel it ought to have many other applications from its extreme hardness.

Dr. Hopkinson's experiments on the magnetic susceptibility of manganese steel were referred to by Prof. Barrett, who mentioned that he had only seen them after his paper had been written. Though Dr. Hopkinson's method of experiment was wholly different, his result is fairly in accordance with the numbers obtained by Prof. Barrett for the ratio of iron to manganese steel.

Prof. Barrett determined the tenacity of the manganese steel wire. The hard wire had the extraordinary tenacity of 110 tons per sq. inch, or 164·5 kilos. per sq. mm., a number confirmed by independent tests which the chief engineer of the Great Southern and Western Railway Works (Mr. Ivatt) had kindly made for Prof. Barrett. Ordinary steel is only 99 kilos. per sq. mm., pianoforte steel wire alone showing a higher tenacity. The soft manganese steel wire had a tenacity of only 48 tons per square inch with an elongation of nearly 20 per cent.

The modulus of elasticity was also determined by Prof. Barrett by direct stretching. It was even lower than wrought iron, the mean number for the hard manganese wire being 16,800 kilos. per sq. mm., the soft manganese wire having a still lower modulus. The modulus for ordinary steel wire is 18,810, and for iron wire 18,610; so that though hard manganese steel has an enormous tenacity, it "gives" more than steel under sudden stress, of course recovering itself if the limits of elasticity are not passed, a property most useful for certain purposes.

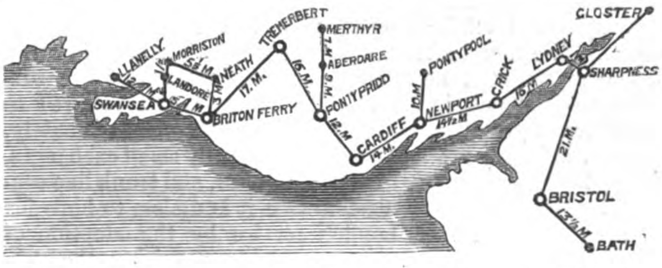
Further experiments on this interesting material are in progress in the Physical Laboratory of the Royal College of Science, Dublin.

THE TELEPHONE IN THE WEST OF ENGLAND.

The Western Counties and South Wales Telephone Company commenced operations, as an offshoot of the United Telephone Company, in the year 1878. The district over which it is exclusively licensed to make use of the patents of the parent company comprises the counties of Somerset, Gloucester, Hampshire, Wilts, Dorset, Devon, Cornwall, Worcester, Hereford, Monmouth, and the whole of South Wales. An exchange was opened at Bristol in the month of March, 1879, with 25 subscribers. The number of subscribers upon the list at the time of a visit which we recently paid to the exchange was 380, in addition to which a number of private lines have been erected in this city. It was not until five years later that the company extended their operations to other parts of their district, but within the last two years very rapid progress has been made, as will be evident from the following table, showing the present position of the company's operations in the nine towns in which they are now represented :—

Exchange.	No. of subscribers connected.	Daily calls	Average per subscriber.	Date of opening of Exchange.
Bristol	380	2,533	6·6	March, 1879
Plymouth	126	475	3·7	February, 1885
Torquay	50	69	1·3	August, 1885
Portsmouth	88	321	3·6	July, 1885
Cardiff	29	149	5·1	November, 1885
Bournemouth ...	89	146	1·6	March, 1886
Southampton ...	35	140	4·0	June, 1886
Swansea	18	17	0·9	August, 1886
Bath	13	25	1·9	November, 1886

At the same time the company wisely decided to turn their attention to the question of inter-urban, or long distance communication. Having obtained the necessary licenses from the Postmaster-General, it was determined to go in at once for a comprehensive scheme which should place the whole of the South Wales mining district in communication with the seaports of Swansea, Cardiff, and Newport, and these in turn with Gloucester, Bristol, and Bath. The accompanying sketch map



shows the course of this system of trunk lines. This extensive undertaking was nearing its completion, and the lines would have been opened throughout early in the present year, but we regret to learn that the disastrous storm of Dec. 26th has inflicted some damage to the wires, and the date of opening will have to be postponed for some little time.

In addition to this system another almost equally extensive is projected in the south. This network will have Salisbury for its centre, and will extend a series of radial wires to the towns of Winchester, Southampton and Portsmouth, Bournemouth and Poole, Dorchester and Weymouth, with probable further extensions westward, and a main trunk to Bristol. The scheme will be proceeded with in the course of the summer. Further plans have as yet hardly been definitely formulated. It is, however, hoped to establish a third network in the counties of Devon and Somerset, and then to connect this with Bristol and Salisbury, and eventually, if possible, to place the whole in communication with London. Some experiments which were recently carried out upon the Great Western Railway lines on a Sunday morning, when the telegraph traffic was very light, showed that, even under the unfavourable conditions of an iron wire and an earth return, it was possible to speak from Exeter to London without much difficulty, while between Bristol and London the communication was quite satisfactory.

Returning to the work already carried out, the following short trunk lines are in actual operation :—

Bristol and Bath........................	13½ miles.
Cardiff and Newport	14 „
Bournemouth and Poole	6 „
Swansea and Llanelly	12 „

In addition to which a line of 8 miles from Worcester to Great Malvern, and one of similar length from Weymouth to Dorchester, will very shortly be ready.

The total length of the South Wales trunk line from Bristol to Llanelly is 128½ miles, the respective distances from Bristol of the chief places on the line being as follows :—

Sharpness Docks	21 miles.
Gloucester	39 „
Newport	52½ „
Cardiff	66½ „
Pontypridd................................	78½ „
Treherbert	94½ „
Briton Ferry	111½ „
Swansea	116½ „
Llanelly	128½ „

The Newport and Cardiff line, which was the first to be erected, consists of a solid galvanised iron wire, No. 11 B.W.G., having a resistance of 24 ohms, and a weight of 200lb., to the mile, with a breaking strain of 520lb. The later trunk lines are all built of hard-drawn copper No. 14 B.W.G., having a resistance of 8·28 ohms, with a weight of 110lb. per mile, and a breaking strain of 360lb. For the local lines (in addition to the last-named) three classes of wire are now in use, No. 15 hard-drawn copper, No. 17 silicium bronze, and a 3-strand No. 16 iron wire.

It may be mentioned that the gross rental of the company now approaches £14,000 a year, and shows an increase of about

Digitized by Google

£4,500 during the last twelve months. This satisfactory state of things is due, in a very large measure, to the great energy and determination displayed by Mr. H. F. Lewis, the secretary and general manager of the company. But Mr. Lewis has not only succeeded in bringing the financial affairs of the company into a sound and progressive condition, he has also introduced certain improvements into the working of the Bell switch-board which render the Bristol exchange one of the most rapid and efficient which it has ever been our lot to inspect. We found after several careful timings that fourteen seconds represented the average interval required for a subscriber to get "put through." The improvement referred to is a matter of *procedure*, and not of appliances. Unfortunately, however, it is only available for comparatively small exchanges, where all the lines are carried to one board, and trunk line connections are not very frequent, so that it is useless to hope for any improvement in the London service by the adoption of this plan. The improvement consists in requiring the subscribers to give *their own* number as well as that of the connection required. By this simple device it is never necessary for the "board operator" to speak to the "table operator" at any time, except in the event of a wire asked for being already engaged. At the Bristol exchange there are three board operators at work, each with two tables placed close behind her, and the sole communication which passes in the room for each connection made is the announcement of the figures representing the number asked for by the subscriber. Of course, the table operators have to speak to the subscriber, but at the time of our visit, although the annunciator drops were falling fast and furiously, yet the room gave one the impression of perfect quietude in comparison with the switch room of an average telephone exchange in this country.

Having regard to the efficiency of the service it is not surprising that the telephone is very popular in Bristol, even among those who have not as yet availed themselves of the service, although there is plenty of room in a city of 200,000 inhabitants for at least ten times the present number of subscribers. We may add, in conclusion, that all the fire stations and many of the cab rests are connected with the exchange, and that the Watch Committee have under consideration a scheme submitted by the chief constable for erecting a system of police call boxes throughout the city.

THE "UNION" STORAGE CELL.

Under the above name, the "Union" Electrical Power and Light Company are introducing a new type of secondary battery. So far as we have been able to form an opinion from a careful inspection of the cell and our knowledge of the properties of the material which forms the cathode, we venture to prophecy an important future for this battery. The cathode consists of a solid slab of peroxide of lead, which is so prepared as to assume a highly coherent form, in which, moreover, it is an excellent conductor of electricity. At the same time the slab has a sufficiently porus texture to present a very large effective surface. Contact is made with the electrode by means of a slip of platinum foil, over which is laid a thin strip of celluloid, the whole being secured to the surface of the peroxide by means of two bolts of insulating material. Owing to the conducting power of the peroxide and its solid condition no lead supporting plate is necessary, and hence there is no tendency to buckle or to short circuit. The positive element consists of a slab of spongy lead. In order still further to increase the output for a given dead weight, internal cells made of celluloid are employed, which are placed in plain wooden boxes. The result is that according to the statement of the company a capacity of 5 ampere-hours per lb. of total weight has been attained. This is a very marked advance, and should render the battery well suited for use with miners' safety lamps, as well as for heavier work, where a portable battery is required, such as for tramcar and torpedo boat service. A further advantage obtainable by the use of this particular type of cathode is that *both* plates may be removed from the cell, and may readily be transported to any required distance for recharging. The company therefore proposes to supply batteries for electric lighting upon the system of removal for re-charging. It is, moreover, pointed out that as the peroxide plates may be stored in the dry state, a third set of plates ready charged may be kept always at hand, so that in the event of any abnormal discharge the installation will not be dependent upon the punctual removal of the plates.

DEATH OF SIR FRANCIS BOLTON.

It is with profound regret that we have to announce the sudden death of our much esteemed fellow worker Colonel Sir FRANCIS BOLTON, who expired late on Wednesday night at the Bath Hotel, Bournemouth, where he had been staying for the last two months in the hopes of being cured there of a malady which he, at all events, never appeared to regard as of a very serious character. His loss will be profoundly felt, not only among his personal friends, who are exceedingly numerous, but by the scientific world, on whose behalf he was an indefatigable worker and staunch patron. Sir FRANCIS was publicly known, more particularly as Water Examiner for the Board of Trade, a post which he has held since 1871, and as the contriver of the illuminated fountains at South Kensington annual Exhibitions, a work which was under his personal supervision to the last. But the electrical world will remember him best by the part he played in founding the Society of Telegraph-Engineers, to which he has rendered many valuable services, and of which he has been the honorary secretary all through its career. As a sample of his industry and the intelligent interest he took in electrical inventions we have only to refer the reader to the remarkably exhaustive abstracts of electrical patents in the papers he contributed to this society. Sir FRANCIS BOLTON entered the army in 1857, and was the inventor of the visual signalling system which now prevails in Her Majesty's service. He has been on the retired list since 1881, and died at the early age of fifty-six. From an obituary notice which appeared in the *Globe* last night we extract the following:—"Sir Francis had for a long time past been an acute sufferer, the symptom of his disease which gave most trouble being an almost total loss of voice. In the hope of improving his condition he underwent several operations, but with little result, and experienced considerable pain, notwithstanding which he invariably appeared in the best of spirits, and frequently made jokes at his own expense in reference to his loss of voice. Sir Francis was in appearance of somewhat burly build, and had a fine presence. He was exceedingly popular with all who came in contact with him, and his bearing towards his *employés*, even of the lower grades, was such as to render him exceedingly popular with them also."

CORRESPONDENCE.

WAS IT UNDULATORY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your comments on page 161 on the make and break transmitter invented by Messrs. Dann and Lapp, you rightly observe that if there is self-induction in the circuit, however abrupt the make and break may be in the transmitter, the current in the receiver will still be of an undulatory character. That is indisputable, and it therefore follows that, even on the supposition that Reis's telephone was to be used as a make and break instrument (though he never said that such was the case), he used currents of an undulatory character in his early instruments. This is the very point on which the American judges have been hopelessly and wilfully misled by the wily and unscientific theories of 'cute Yankee attorneys. Not one of the United States judges understands anything about self-induction, or they would see that even a make and break transmitter pure and simple must produce an undulatory current such as Reis required and Bell claims to have been the first to have invented.—Yours, &c., ALPHA.

THE VALUE OF TELEGRAPHIC COMMUNICATION IN TIME OF WAR.

Sir James Anderson contributes the following letter on this subject to the January issue of *Imperial Federation*:—

SIR: In your editorial remarks in the December issue upon my letter about Cables, Colonies, and Commerce, you suppose me to mean that the two latter may be "shelled and smashed" if the cables are cut.

It is, I admit, not a pleasant thing to say, but if it is the truth it had far better be said, and I think it cannot be too strongly insisted upon, that it is folly to depend upon submarine lines, *laid in time of peace*, and projected as they all are upon the charts of all nations, remaining intact in time of war.

It is reasonable enough to rely upon such conditions until war is about to be declared; but whenever that time seems near then I do assert very positively that a dozen Alabama-like craft can be very quickly made ready to cut as many cables as may be desired.

For cutting purposes it is not necessary to think of long distances or employ large vessels. The ships destined to cut can select their own place and time, and it is just as easy to go to a given latitude and longitude, out of sight of land, where a cable is known to be lying, *and find it*, as it is to go to any distant headland or lighthouse.

You say you are quite content to have the issue raised upon the question of the "*time when*" other cables should be laid, and you "advocate having two strings to our bow at once, so as to be ready when war is imminent."

My contention is that laying cables from Vancouver to Sydney, or the Cape to Australia, is more accurately described as a fifth wheel to the coach than as two strings to the bow. When laid their position will be known, and they can be found and cut by any one so disposed.

I have, in a paper read before the Delegates of the Chambers of Commerce, at the Colonial Exhibition, given my views of the only conditions which offer any alternative to this statement, and I do not believe any one familiar with the subject will gainsay what I have advanced. Briefly, I put it thus:—

The enemy must realise that it is no use cutting cables, because there are so many other routes through neutral countries by which telegrams can be sent, that to interrupt the communication would only create an unimportant inconvenience, and would not affect the result of a campaign. There may also be cables owned by nations who are no parties to the quarrel, and who are strong enough to demand that their cables shall not be cut; and all nations may now feel assured that strategic cables laid, when required, in a position not known to the enemy, will form part of the equipment of any naval power engaged in hostile operations. I should be very glad if I could think of any protection for cables other than I have already defined in this and in my letter in your December issue.

At the risk of presuming too much on your space, I should like to state what I believe will be the position of our commerce, coaling stations, and colonies, when war is about to be declared between this country and any other possessing a fleet of cruisers.

Our shipowners will insure if they can—paying for war risks.

All sailing ships must either sail under neutral flags or be laid up in dock in the safest port they can reach. All steamships continuing under the national flag will be informed by the Admiralty of the track they must follow, and the given latitude and longitude where they will find our cruisers or other war ships.

An inevitable feature of every plan for the protection of our commerce will be the *restriction* of our commercial marine to our fastest steamers and the *concentration* of our war ships and cruisers—and I pray the latter may be belted, for such craft as the "Iris" or "Mercury," "Etruria" or "Alaska," have only one chance if struck by a shell—which is, that the shell may go through both sides and into the water before it explodes, or the gun deck will be a shambles. I can suppose such craft acting as eyes to the fleet, and we may hope that their superior speed will enable them to return to our fighting squadron before they are attacked by an enemy's war ship; and they may lure the foe to a position in the open sea where a battle can be fought with perhaps some advantage to our fleet.

It may be supposed also that they would count for a good deal with an enemy who had few or none so good; but it is for keeping open communication, for the transport of troops and stores, that they will be chiefly valuable.

I do not believe in merchant steamers being reliable war ships, and I am as disappointed when I see such ideas advanced as I am delighted when I read of the launch of another belted cruiser.

I cannot believe those responsible for the defence of our Empire are not prepared to provide all coaling stations with such means of defence and weapons for offensive warfare as will ensure the flying squadron of the enemy a warm reception. It would be an insult to our Admiralty and War Office to suppose that they are relying upon either our war ships or cruisers to be insufficient force at more than a few of our principal coaling stations at one time to meet any considerable enemy. To follow an enemy is to exhaust the coal supply, and to concentrate a number of ships by telegraph is certain to bring some of them to the desired spot with their coals exhausted; then, if they cannot get a fresh supply because of the strength of the enemy, they will easily be "nursed" and captured.

We shall probably know where to look for the enemy, and especially we will seek him at his coal-supply rendezvous, and endeavour to keep him there or capture him; but to do this effectually our own coaling stations must be in a position to guard themselves against a surprise.

The same must be said of all our colonies, and I feel I am only writing what is well understood by those who are responsible, but I cannot help seeing how very imperfectly the position is recognised by the public. The concentration of our fighting power upon a well-matured plan, with as little necessity as possible for spreading out in distant oceans, must be the very essence of any arrangement. Coal supply and coal endurance will be the test of naval supremacy.

Then as to commerce, it goes without saying that from the moment war apprehensions are in the air, all engaged in financial transactions will restrict their engagements to the utmost. They will not trust to cables, but prepare beforehand for the worst.

Very little will then depend upon the Mediterranean cables. We can get to the shores of that sea through Spain, France, Italy, Austria, Greece, and Turkey, and if we cannot with our naval resources keep fast cruisers to cross the Mediterranean to Egypt, then indeed we shall be engaged in a terrible and calamitous war, and what commerce there is will be carried to and fro under other flags. But I for one do not think that day is very near.

At all events the long submarine cables proposed will do nothing at all to diminish the danger (which is the only point of difference between us, in your opinion).

I maintain, then, that the "*time when an alternate line should be laid to meet the exigencies of war*" is only *when* we have determined with whom we are going to war, and where we are going to fight him. Much, very much, can then, and in anticipation, be done to ensure communication, but the very worst plan of all is to lay long, expensive submarine cables in the deepest oceans, in which it is almost impossible, and always tedious and costly, to effect repairs when the cables are old, or have been cut or broken.

Better far use the money to reduce the tariffs, thereby increasing our commerce and adding to the wealth of the whole Empire, which is one of the best preparations for war, and will do more for Federation than any other scheme which has yet been or, I believe, can be formulated.

Upon this letter the Editor makes the following remarks:—

A New Pacific Cable Route to Australia.

Sir James Anderson has returned to the subject of ocean cables in a letter which we publish in another column. Since our last issue the matter has practically passed the stage of argument, and it is therefore unnecessary for us to follow it up further. We are glad to hear that a powerful company has been formed, with a capital of £2,000,000, to establish a telegraphic line between the Australasian colonies and Vancouver. This will spare us the necessity of further allusion to the weak places in our communications, which will soon be doubled in strength and efficiency by the possession of an alternative route.

Sir James Anderson's letter is interesting, as giving the opinion of an experienced man upon the probable results to our commerce of an outbreak of hostilities with another Power. His suggestion that neutral lines of telegraph would be available opens the field for some nice questions as to the laws of international neutrality in time of war. But where are these neutral lines? If any agreement could be arrived at to neutralise all cables, the case would be different, but there does not seem much prospect of this, and at present there is but one route to Australia. We want to see *two*, and we shall not be kept waiting long for the event.

As for the proposition that the time for laying an alternate line is "only when we have determined with whom we are going to war, and where we are going to fight him," we really cannot understand it at all. What we want is to make certain of being able to flash out the instructions to every port in the Empire, "Lay down your mines," the moment the hostilities are imminent. No one can gainsay the vital importance of having this power. No one can reasonably deny that, whether cable-cutting be easy or difficult, the possession of two routes gives a twofold chance of forwarding intelligence that may save millions of pounds' worth of property from destruction.

We believe that a Pacific cable route would, in fact, do more than double our chances, because we have no great faith in any foreign squadron being found on the high seas so far from port, if war with England was expected. But admitting one route to be no more secure than another, the mere numerical addition to our possible means of communication would well deserve all the support that can be given to it, and the safety of the Empire emphatically demands that the addition be made without delay.

1886.

Twelve months have passed, and yet it seems but yesterday we were discussing the then position of electrical science. The time has come round again when it is customary in these pages to pass under review the work of the past year. Can the most staunch believer in the progress of electrical science or its applications look upon 1886 as presenting any phenomenal acquisition to the annals of electrical progress? We, who have to watch closely the daily work in every department of pure and applied electricity, are fain to give precedence to the results which have arisen out of the reading of Mr. Kapp's paper, at the end of 1885, before the Institution of Civil Engineers. Dr. J. Hopkinson, on the reading of this paper, suggested certain methods of measurement as applied to dynamos, and, with his brother, Dr. E. Hopkinson, has, during 1886, if we may so speak, perfected the suggestion. We look upon the work of the Brothers Hopkinson and of Mr. Kapp in the direction of the fortelling the characteristics of a dynamo as the natural outcome of the previous paper. There is no doubt these men have done more to make the "specification of dynamos" an exact art than all other investigators besides. Progress in other directions has been decided though moderate, and is found principally in the perfection of details.

In our estimation the time has come when the initial stage —the rule of thumb stage—may be said to have passed away, and future comparisons should be made with the practice which holds at the beginning of 1887, and not with the practice that has gone before. It is suggested in some quarters that the Gramme ring armature will in the future give place to the Siemens drum type of armature. We have not now to discuss the comparative advantages of one type of armature over another, but will say that, leaving this out of question, the general type of dynamo has been obtained. Given the type of steam engine to be employed, a pretty exact specification is soon forthcoming when a purchaser requires an engine, and so it will in the future be with dynamos, fairly exact specifications being forthcoming when the work to be done is known; in other words, dynamos will in future be built from detailed specification. We do not wish to be misunderstood, and to be held to say that further progress is impossible. On the contrary, we believe that perfection will never be reached, and improvement will be more or less continuous. Already, in that fact, we hear rumours of suggestions and investigations that may revolutionise the construction of dynamos. Undoubtedly, every part of the machine will receive closer and closer attention, and although we may be supposed to be the staunchest supporters of modern theories as regards electricity and magnetism, *we are thoroughly convinced that the correct theory has not yet been promulgated.* Critically examined, there is no single theory advanced to account for the phenomena but is exceedingly cumbersome and fails at various points. Believers in a "mode of motion," in an "entity," in action in a conductor, in action entirely outside the conductor, who speak learnedly of strains, of stresses, of vortices, &c., must all feel at times that there is something yet they do not understand, and which, if they could only grasp, would greatly simplify matters. The nineteenth century will leave something for the twentieth century to do; and if we could but know ourselves as our descendants a thousand years hence will know us, we should probably be a little less troubled about orthodoxy and heterodoxy in matters scientific.

One important feature, from a business point of view, of the past year is in the increased manufacturing competition. The protection of the Gramme patent having expired, many firms concluded that they could make dynamos as well as older establishments. This was expected, and we are not sure that it is an unmixed evil. At any rate we are sure that in these days, when money is less easily made than it was in the times when "booms" reigned supreme, purchasers will consider not only first cost, but also cost of maintainence, and will not for long be tempted to patronise a maker whose machines are cheaper in the beginning, but infinitely dearer in the end. We must continue to warn our readers against being led astray by the difference of a few pounds in price lists; an extra hundred weight of coal per day because of lower efficiency, or more lubricants because of a badly balanced machine, soon counterbalances the initial saving. The older firms, however, are being taught that they will not have matters their own way, for the younger ones, by tact and energy, are obtaining a footing in places where one would not expect to see them.

Our introduction has hitherto spoken almost entirely of dynamos and dynamo construction, but the applications of electricity are by no means included in this one subject. It would be better perhaps to divide the whole subject under various headings, such as—1. Telephony. 2. Land telegraphs. 3. Cable work. 4. Electro-chemical and metallurgical industries. 5. Electric lighting industry.

I.—Telephony.

From the scientific point of view 1886 has little or no interest, but 1887 promises better things. A good deal of quiet work has been done, some of which was indicated by Mr. Preece at the late meeting of the British Association. Other

Digitized by Google

information will, we understand, be forthcoming at one of the meetings of the Society of Telegraph-Engineers during this session. We shall content ourselves, then, with giving the commercial position of telephony so far as we can ascertain it. The largest company withholds all information; no doubt, because it thinks we are in the wrong as to our policy on the question of overhead wires. Well, the shareholders even of the United Telephone Company may wish one day they had listened to us, and sent those men adrift who persisted in the suicidal policy of overhead wires. Another storm of snow and wind about March, when the repairs are just completed, would be almost sufficient for our purpose, and compel another system to be adopted. How subscribers like having to pay in advance and not getting their money's worth is more than we shall attempt to decide. In London, at any rate, grumbling is a privilege that may well be indulged in at the present time. The energy thrown into the work by the various companies outside the metropolis is altogether a different quantity, and it is mainly from them that progress will come. The papers referred to above will be contributed by officers of the Post Office Telegraph Department and of the National Telephone Company respectively.

The NATIONAL TELEPHONE COMPANY is progressing steadily, as will be seen by a comparison of the following figures with those given in our annual article last year :—

In Hanley, Stoke, Burslem, Longton, and Tunstall £12 subscription gives right to speak to any subscriber in the five towns.

The connections between Glasgow and Falkirk, Falkirk and Stirling, Falkirk and Grangemouth, Boness and Linlithgow and Edinburgh, Stirling and Bridge-of-Allan, Alloa and Tillicoultry are either completed or will be so during the next few weeks. Also between Glasgow and Helensburgh.

Conversations may be held from any exchange in Yorkshire to any town connected to the Trunk line system of the Lancashire and Cheshire Telephonic Exchange Company.

One hundred and forty-two call offices from which the public can speak have been established throughout the system.

Other important Trunk line connections are in course of construction, and several contemplated lines will be built on sufficient support being obtained.

Conversation may be held between any of the towns on the list which are "bracketed."

Carrickfergus, Whiteabbey, Newtownards, Holywood, Comber, Dunmurry, Lisburn, and Hydepark are connected to Belfast.

Hanley, Stoke, Burslem, Longton, and Tunstall are connected.

THE LANCASHIRE AND CHESHIRE TELEPHONIC COMPANY is a very go-ahead undertaking, as will be seen from the following statistics :—This company has about 7,000 miles of wire working, of which about 2,500 miles are trunk lines for intercommunication between towns. The Yorkshire section of the National Telephone Company's district has recently been placed in connection with this Lancashire and Cheshire system; and, by arrangement between the two companies, it is expected that the National Company's Pottery district will also be placed in communication at an early date. Further, the Northern Telephone Company's Newcastle and Sunderland district is expected before very long to be linked-up to the National Company's Yorkshire system, and thence to the Lancashire district. The rates shown are the "business" charges and for distances within a mile of the company's "centre" in the respective towns. After the first mile the additional distance is charged at the rate of £7 per mile in all the towns. Besides the "business" scale, there is a "domestic" one, by which the subscribers to the Manchester or Liverpool city systems (£20) can have their residences joined up at £12. per annum. Subscribers in the £12 towns pay proportionally. Then there is a "multiplex" system, recently introduced,

Digitized by Google

whereby several persons may join at the use of one wire. This system, so far, is only in operation in Manchester and Liverpool, where the £20 subscription (ordinary) becomes £12 on the "multiplex;" but other towns will shortly have this new system introduced, and at proportionate rates. The popularity of the trunk wires and public call offices may be judged from the fact that in less than two years the company has reached an income, from these sources alone, of £6,300 a year. The "exchange" and private line income, including orders in hand not completed, is about £79,000. Quite 50 per cent. of the subscribers make regular use of the trunk wires, and the average daily "calls" reach 2,750 for trunk lines, as compared with 22,000 purely local. All the statistics herein are as at 24th December, 1886.

The Lancashire and Cheshire towns marked thus (a) are in trunk-wire connection with each other, and also in connection with the following Yorkshire towns:—Batley, Bingley, Bradford, Brighouse, Cleckheaton, Dewsbury, Halifax, Hebden Bridge, Holmfirth, Huddersfield, Keighley, Leeds, Morley, Ossett, Penistone, Pudsey, Rawdon, Sheffield, Shipley, Skipton, Sowerby Bridge, Stanningley, Wakefield.

(b). Altrincham and Bowdon, Leigh and Tyldesley, Macclesfield and Ramsbottom not yet opened, but expected to be at an early date.

(c). Barrow, Dalton, and Ulverstone have a "group" system of trunk-wires connecting these three towns only.

The New Telephone Company.—This company, it may be said, has hardly got into harness as yet, but during the year it has, amongst other installations, supplied the Bessbrook Spinning Company, at Bessbrook Island, with ten instruments. Considerable difficulty was experienced there in consequence of the induction from the electric railway, alongside which the telephone lines were run. The installation, however, was successfully accomplished, and some credit is taken for this in that the Bell telephone had been previously tried and found wanting. At Broadmoor Asylum fifteen sets of instruments have been installed by Messrs. Paterson and Cooper, under the supervision of one of the company's staff. Messrs. Wernham and Waters, of Croydon, have been supplied with thirteen sets for the public offices in Jersey. At Poole, Messrs. Bailey and Sons' installation has continued to work well through a line of five miles in length, from Poole to Bournemouth. Instruments have been put up at Whiteley's, Westbourne-grove, and at Messrs. Huntley and Palmer's, at Reading.

In Lancashire and in Yorkshire the local agents have put up many private installations, and numerous applications have been made for the establishment of exchanges. At the present time the company is actively canvassing in Chelsea, where it is proposed shortly to open an exchange; and no doubt when we come to chronicle the work of 1887, the progress of the company will have been found to have taken place as rapidly as expected.

The South of England Telephone Company has exchanges in the below-mentioned towns. It may be recollected that Brighton is in telephone connection with London:—

Town.	No. of Subscribers' Lines. Exchange.	Private.	Trunk.	Totals.	Exchange Tariffs.
Brighton...	274	65	14	339	£12
Eastbourne	48	17	—	65	10
Hastings...	76	16	—	92	10

The Northern District Telephone Company, with head-quarters at Sunderland, has the following position:—

Towns.	No. of Subscribers' Lines. Exchange.	Private.	Totals.	Ex. Tariff. Per Ann.
Sunderland	215	31	246	£14
Darlington	11	1	12	12
Durham	6	4	10	12
East & West Hartlepool.	35	3	38	12
Middlesbro'...............	56	13	69	12
Newcastle-on-Tyne	54	22	76	12
North Shields	5	4	9	12
South Shields, Tyne Dock	22	6	28	12
Stockton.....................	26	2	28	12
Bishop Auckland	—	1	1	—
Alnwick	—	1	1	—

Subscribers in Newcastle can speak free to Sunderland and *vice versâ*; subscribers in Middlesbro' can speak free to Stockton and *vice versâ*.

It is intended shortly to join this Company's system with that of the National Telephone Company and Lancashire and Cheshire Telephone Company.

Sunderland, Darlington, Durham, East and West Hartlepool, Middlesbro', Newcastle-on-Tyne, North Shields, South Shields, Tyne Dock, and Stockton, are connected together by trunk wires.

Digitized by Google

The Telephone Exchange Company at Sheffield is in the position as below:—

Town.	No. of Subscribers' Lines. Exchange.	Private.	Total.	No. of Call Offices.	Exchange Tariffs.
Sheffield...	343	54	397	12	£10

The Western Counties and South Wales Telephone Company is referred to in our other columns, in an article which has been for some time in type, but which has hitherto been crowded out by press of other matter.

V.—Electric Lighting.

Our attention this year has been directed to the getting together illustrations of the types of dynamos now made rather than towards the recording the actual installation work done during the year. However, we have before us a fairly exhaustive account of such work, and may be permitted to refer to some of it before coming to the dynamos. Before this, again, must come a brief reference to legal matters. *The* legal topics of the year have been, so far as electricians are concerned, "incandescent lamp patents" and "compound winding patents." The case of "Edison-Swan *v.* Woodhouse-Rawson" went in the first part to the Edison-Swan combination—the result of the second part is not yet known. Meanwhile, the Brush Company guaranteed to indemnify the users of their Victoria lamp, in the production of which new processes have been introduced; and Mr. Bernstein, as will be seen from a report given in another column, has modified his original methods because of the trial. The question of compound winding is still *sub judice*, though several of the manufacturers have, in schoolboy parlance, "caved in," becoming licensees of the Brush Company.

A correspondent, Mr. S. F. Walker, writes at considerable length about the present condition of legal and patent questions. We are fain to let Mr. Walker speak for himself, pointing out that while such an eminent scientific man as Mr. J. F. Moulton is almost always engaged as one of the counsel in these technical cases, there is not much danger of judge or jury going scientifically astray. Although, John Bull like, if we had an opinion we should probably try and stick to it, if Mr. Moulton disagreed with us after careful investigation, we should be rather inclined to imagine we "might be mistaken." And again, we must admit our judges to be somewhat akin to other eminent and well educated men, therefore it is but just to suppose they are fairly well acquainted with many matters scientific. Perhaps one would not suspect the Prime Minister of England to know much about scientific matters, yet if some of the professed practical and scientific men were pitted against him they might find to their astonishment that he knew more than they. Lastly, it must never be forgotten that so-called "expert witnesses" appear on both sides, and their statements are as wide as the poles asunder. The "expert witness" is our *bête noir*; but we have always before us the constructive difficulty. We cannot easily suggest a better system, though we rail against the present system. Those who think with Mr. Walker—and we have reason to know their number is legion—will perhaps tackle the difficulty, and if any one succeeds in solving it, the space occupied with this lament will not be wasted. Mr. Walker says—

"You may perhaps allow me a small space to point out what in my opinion is likely to interfere more than anything else with the progress of electrical engineering. I refer to the, as it appears to me, very unjust administration of our Patent Laws. How long, Sir, are our law courts, when engaged in the trial of a scientific patent case, to be the laughing stock of the scientific world? Is it not absurd on the face of it, that where hundreds of thousands of pounds, perhaps, are depending upon a just judgment between rival claimants, that their claims should be argued by a brace or a quartette of advocates who have only the most superficial knowledge of the subject, before a judge who knows absolutely nothing of it? I remember, in my very young days, when the results of examinations were important factors in my future, hearing it stated that the perfect idea of an examination was, that the examiner was supposed to know nothing, and the examined were to teach him. I believe, Sir, that if students coming up for examination were perfect in their subject, this would be by no means a bad test. As matters stand the universal practice is, so far as I am aware, to appoint as examiner the most capable man obtainable in that special subject. That is to say, where the question is whether John Jones shall pass, or he or John Brown shall have the prize, every care is taken that the judge thoroughly understands every detail of the subject. Where, however, the question is one affecting very large sums of money, often the welfare and the comfort of very large numbers of people, and where one would think even greater precautions should be taken, the *examiner*, to our disgrace be it said, is perhaps the only person connected with the case who is profoundly ignorant of the subject. At any rate he must, except in special cases, know least of anybody in court. Would it not be simpler to entrust the decision of such cases to a trio of schoolboys? With the English schoolboys love of fairplay, and with their young brains unbefogged with the contents of those proverbially dull, musty folios, that are said to contain common sense—if you can only find it—we should at least be sure that no unfair advantage would be taken by either advocate. I have no doubt it will be said that the judge decides on the evidence before him, and that his legal mind is trained to balance the opposing opinions, &c. The assumption here is that a judge trying a patent action is in the same position as when he is trying, say a property action, a will case, or a criminal action. A little thought will, I think, convince everyone that this is not so. Trying a will case or a property case, he has either to decide on the balance of evidence as to actual facts, or as to the meaning or proper application of certain words in a document; and here his whole legal training comes in to aid him. He is like an old gladiator watching the exercises of younger ones. The heirs of male entail of the tenth earl, or the eleventh duke, and all the musty legal phraseology that so bewilders us, is as familiar to him as volts and amperes are to us. And in a criminal action a similar reasoning holds good His training and experience tell him intuitively how to hold the balance, so that there shall be no undue weight on either side; and, moreover, he is familiar, from his pre-judicial practice, with the manner in which prosecutions and defences are got up, and can rightly appraise the value of a witness or the argument of an advocate. But turn to the case of patent actions. A judge may have to decide one day between two rival gas engine makers, when perhaps he has not an idea what a gas engine is; next day between two makers of ordnance; and the next one a sweeping electrical patent, such as our American cousins claim and their English owners endeavour to enforce by every means that money will furnish. Now, Sir, I will ask any reasonable man to say if it is humanly possible that any man, however gifted—and I may here mention that our judges may be taken to be among the most gifted men of their day—could acquire merely from what a witness can say in court, and the opposing counsel cannot make him unsay, sufficient knowledge of each of the above subjects to enable him to give a just judgment upon the exceedingly knotty points that

Digitized by Google

always arise? How many of the readers of *The Electrician* thoroughly understand, for instance, the working of a gas engine, or of an automatic expansion steam valve? To show the absurdity of the matter more clearly, what engineer is there who would venture to give a judgment upon some knotty legal question? What a thorough contempt the gentlemen of the long robe would have for any one of us who tried. Can they understand what a thorough contempt we have for them when they make the childish blunders that are inevitable to a man arguing upon a subject he knows nothing about? I have no doubt it will be said, further, that it is the experts who decide the case; or, rather, the judge, from what he has gleaned from their evidence. I confess that I have been struck with the great ability exhibited in the judgments pronounced by some of our judges, and I have wondered how on earth they managed it. The secret will be found, I think, in this, that the judgment is usually based upon the evidence of some witness who has secured the ear of the judge, and whom the opposing counsel has been unable to move. It is this witness, then, who really decides the case; but if this is so, is it just that he should be both judge and advocate too. For advocate he undoubtedly is. He is paid to win the case for his clients; and, whether consciously or not, he will view every part of it through the medium of the big fee he has received. Everyone knows that there are at least two ways of looking at every one of the points that arise in scientific patent cases; and the able man who is thoroughly master of his subject, and will take one view and adhere to it, wins the case for his client. But, someone doubtless objects, you forget the opposite counsel and that fearful cross-examination. Well, let us examine this. In the first place, it would certainly conduce very much to the interests of justice if counsel would get it out of their heads that an opposing witness is, as a rule, committing deliberate perjury, or prevaricating. He looks at things from the point of view of his client's interests. But the way to get over that is for counsel to go inside, to examine from inside. But as it is not easy for them to acquire sufficient knowledge to do this, they too often resort to the practice of trying to worry the witness into saying something he does not mean. Now as to the cross-examination, let us see what it means. In many cases it means bullying. But suppose it does not. You have a learned man, in the full dignity of wig and silk, and perhaps in the receipt of a revenue that would be welcome to many a landowner. And facing him stands a man whose name, perhaps, is renowned throughout the world, and who will live in men's minds hundreds of years after the advocate lies forgotten in his grave. What is the advocate now, in comparison with this giant? He is a boy of ten, and he is asking those questions that children of his age are wont to, and that are puzzling to ordinary mortals, and with a view of puzzling—*the Master*. Does it not sound absurd? Cannot we imagine some smart youngster at one of our public schools trying to puzzle the College Don who has come down to examine his class, and the amusement of the latter? I trust, Sir, that an abler pen than mine will take this matter up. The result of our present system is, I believe, in the opinion of the great majority of men who are competent to judge, that grave injustice has been done in very many cases in the matter of scientific patents."

Now to business. Many firms have been fairly busy with installation work during the year. As examples, we may refer to the Brush Company, which has lighted the ss. "Tamar," belonging to the Royal Mail Steam Packet Company, with Victoria lamps, worked by a Victoria Brush compound dynamo driven by a patent "Brush" engine and "Raworth" friction gear; the ss. "City of London," the "City of Aberdeen," and the "Ban Righ," belonging to the Aberdeen Steam Navigation Company, fitted throughout with Victoria lamps supplied by Victoria dynamos, driven by "Brush" engines and friction gear; the extension of the lighting on board the ss. "Orient," where sixty lights have been added, with a Victoria dynamo, driven by Brush engine and friction gear. The corporation have also during the past year fitted up numerous torpedo boats for the Spanish, Dutch, and other Governments with incandescent lamps and search light apparatus, the dynamos being driven by direct acting engines, and they are now engaged in fitting up other vessels in different parts of the world. With regard to the Exhibition contracts secured during the past year, it may be mentioned that the corporation had the largest share of the lighting at the Indian and Colonial Exhibition, where, in addition to supplying upwards of 170 Brush arc lamps of 2,000 candle-power each, they also supplied a large number of Victoria incandescent lamps for the high mast lighting and the dynamos for the fountain illuminations. At the Edinburgh Exhibition a large number of Brush arc lamps were supplied, and the Old Edinburgh section was lighted with their incandescent lamps, with marked success. At the Liverpool Exhibition the corporation supplied through the local contractors, Messrs. Holmes and Vaudrey, upwards of 350 arc lamps, of 2,000 candle power, with Victoria and Brush dynamos, and this exhibition was lighted almost entirely with apparatus manufactured by the Brush Co. Among the public and other buildings lighted during the past year may be mentioned the following:—Drapers' Hall; this installation consists of twin Otto gas engines, running from flywheel on to a Victoria dynamo supplying current for incandescent lamps and arc lamps, storage cells being also employed, arranged two in parallel. The work of running leads for this installation has been executed throughout in accordance with the rules laid down by the Phœnix Fire Office. In connection with the installation at the National Agricultural Hall, now commonly called "Olympia," the corporation obtained the contract for the supply and fixing of all the wires and lamps required for the buildings. The arc lamps are of the well-known Brush pattern, specially fitted and arranged to work from the same wires that supply the incandescent lamps. Fifty-four arc lamps are suspended, in nine groups of six each, from the lofty roof of the grand hall. They also supplied as many as ninety arc lamps of 2,000 candle-power, with necessary dynamos, engines, &c., at very short notice, for temporary lighting during the building operations. This temporary lighting has proved a very great success and convenience, since it enabled the completion of the building to be effected in time, and the plant used for this lighting has since been continued as accessory to the permanent lighting. The Junior United Service Club, Charles-street, S.W., is lighted with Victoria lamps, worked by a Victoria dynamo and storage batteries. The Glasgow Western Baths are fitted with a Victoria dynamo, arc lamps, and incandescent lamps; the dynamo also supplies current for lamps installed in Hillhead Chapel, situated close by. The Uleaborg Hotel, Finland, is fitted with Victoria-Brush dynamos—driven by a Brush engine—Brush-Sellon arc lamps, and Victoria lamps. Among the mill and factory installations may be mentioned the following:—Messrs. Ritchie and Co., Stroud; Messrs. Fox Brothers and Co., Wellington; A. Laverton, Esq., Westbury Mills, Wilts; the Bowness Manure Works; and the following works in the north of France:—G. and H. Barrois, near Lille; Ravinet Frères, Dunkerque; La Société des Moulins de Prouvy; Messrs. A. Lorthios and Co., Tourcoing; M. Avot Vallée, Blandecques. Among the private

Digitized by Google

residences lighted by the corporation during the past year may be noted:—R. Taylor, Esq., Huntsmoor Park, West Drayton; H. Hucks Gibbs, Esq,, Aldenham House, Herts; Abel Buckley, Esq., Rycroft Hall, Ashton-under-Lyne.

A company that has shown great energy during the year, and has been very successful in securing orders, is the Gülcher Company, who favour us with a list of nearly eighty installations completed during the year. In addition to these installations, which have been erected complete, the company has supplied a large number of dynamos for lighting and depositing purposes, as well as a large number of arc lamps. The Gülcher Company, it will be recollected, carried out the lighting at Birmingham during the meeting of the British Association, and, so far as we could see, there could be no fault found with the work. Their installation at the Crystal Palace has been extended by twenty arc lamps in the palace and twenty-two in the grounds. At Edinburgh the company had an installation of sixty-four arcs and seventy incandescent lamps. Altogether the work of the company involved the use of over 500 arc lamps, and nearly 5,000 incandescent lamps, as well as the necessary dynamos. Although several of the installations were for exhibitions, and therefore temporary, the larger number are permanent.

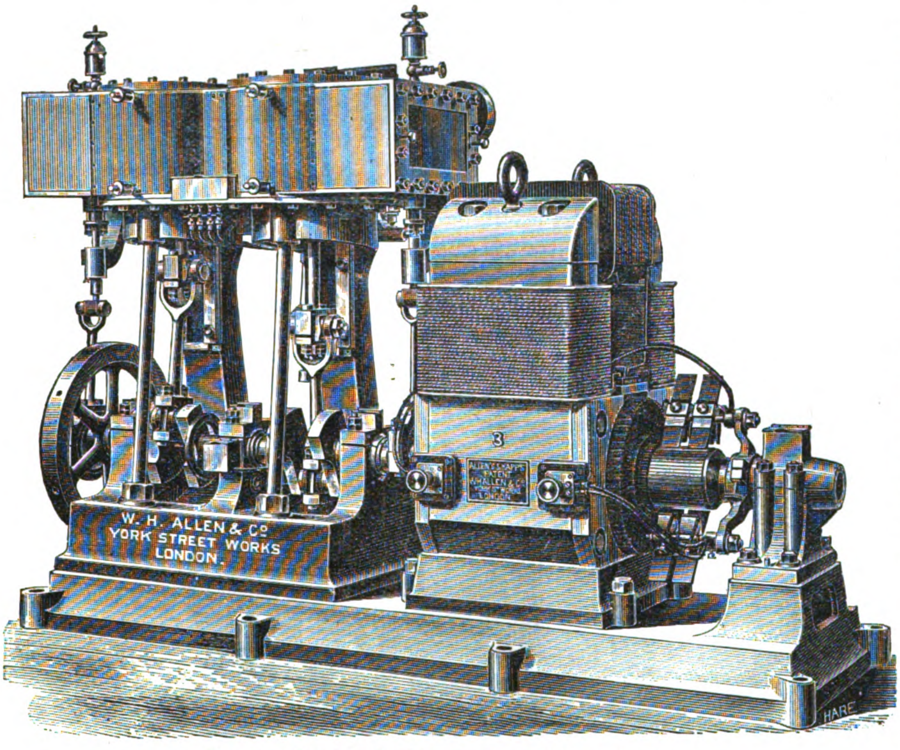

Fig. 1.—Combined Allen Engine and Kapp Dynamo.

Among the country firms Messrs. Walker and Olliver have done a good deal of work in connection with mines. The installation of signalling apparatus is steadily progressing. Electric light installations have been carried out at the New Tredegar Colliery, belonging to the Powell Duffryn Company, where 3 arc and 43 incandescent lamps are used. This is the third colliery fitted up for the company by Messrs. Walker. The Rainston Collieries, belonging to the Marquis of Londonderry, have also been fitted by this firm with 1 arc and 80 incandescent lamps. The Seams Colliery at Gateshead has been lighted both on the surface and underground. The Harris Navigation Colliery has recently been lighted on the surface with 83 incandescent lamps. It may seem that the light progresses slowly in colliery work, but it is satisfactory to find that such companies as the Powell Duffryn are lighting colliery after colliery, showing most conclusively that the system finds favour in their eyes. This firm has adopted the Gramme form of machine, the old type being of course greatly modified which they manufacture.

Sufficient has been said to show that progress is steady in almost all directions. Central station lighting in England is not very prominent, but the year 1887 will probably see this system in actual work at Kensington Gore. Mr. Crompton long ago made us acquainted with the work in contemplation, and we hope soon to be able to commence an exhaustive illustrated description of the scheme. Modifications are, however, necessarily frequent in work of this kind till near completion, hence we prefer to see the dynamos revolving rather than on paper.

We have previously said that the rule of thumb stage of dynamo construction has passed away, and we have endeavoured to bring together into this article illustrations of various dynamos as constructed by different makers at the present time. Readers will look in vain for any reference to some noted manufacturers, such as Messrs. Siemens; but the time is far from opportune for this firm, their machines being in a state of transition. The new designs intended to replace the old are not quite ready, and it is preferable to wait for the new machines than to illustrate the old and well-known type. In the construction of dynamos, so far as commercial and electrical efficiencies are concerned, makers run each other closely. There does not seem to be much chance of improvement in these directions when we hear of 90, 94, 95, and even 96 per cent. efficiency. There seems to be no valid reason why from 90 to 95 per cent. electrical efficiency should not be the rule rather than the exception. The direction in which improvement may be expected is in output for weight within certain limits. There is little doubt but that English makers take the foremost place both as regards efficiency and output for weight, and we trust they will long continue to hold this position.

Messrs. W. H. Allen and Co., of York-street Works, Lambeth, have manufactured during 1886 a considerable number of Kapp dynamos, both for belt driving and for direct driving. A large number of combined dynamos and twin engines, illustrated in the annexed engraving (Fig. 2), have been made to the order of the Admiralty, whilst a few smaller sets have been made to the order of private ship builders for use with search lights on torpedo boats. Another type of combined engine and dynamo, of which four sets were made during the year for ship lighting, is shown in Fig. 1. In this arrangement the engines are twin-compound, and may be worked together or independently, while in the case of a double break-down either engine may work either dynamo. A number of belt-driven dynamos have been supplied to customers in England, Norway, Germany, Denmark, and Italy. In all these machines the magnets are of the simple horseshoe type, placed vertically, with the poles above, and the yoke in the bed-plate.

The Brush Company—which we should call the "Anglo-American Brush Electric Light Corporation," but which we prefer to give, as they do Acts of Parliament, a short title, one

Digitized by Google

that is sensible and usable—has broadly two types of dynamos, each of the main types, however, being subdivided into minor types. Firstly, they have the "Brush" type; and, secondly, the "Victoria" type. The Brush dynamos are now all fitted with the new wrought-iron armature, and hold a leading, if not the leading, place among machines of high E.M.F. for actuating arc lamps or groups of incandescent lamps in series. It may be noticed here, as favourable to the early work of Mr. Brush, that his machine, in the development of the industry, has undergone fewer alterations in design than any other of the early machines. The Victoria dynamo has taken a high place among the modifications of the original Schuckert. During the past year improvements have been made in this machine, increasing its efficiency and reducing its first cost, by increasing the quantity of soft iron in the machine and decreasing the quantity of copper. Victoria machines have been used during 1886 for the purposes of operating Brush arc lamps in parallel, for incandescent lighting, for operating search lights, and the transmission of power. When used as motors they give satisfactory results. Fig. 3 shows the Brush type of machine, and the following figures, relating to a Brush 27-unit machine—*i.e.* a machine to give 27,000 watts—will be interesting, and more so because the increased output is due to the modification in the quantities of iron and copper just referred to, the output of the older type being 20,000 watts, and the E.M.F. at terminals 2,000 volts. The E.M.F. at the terminals of the machine reaches the high figure of 2,700 volts, and the dynamo is intended to be used for 55 arc lamps in series of 2,000 nominal candle-power each. These lamps require 50 volts × 10 amperes, or 500 watts each, the machine giving 10 amperes current at the above voltage when making 850 revolutions per minute.

The total weight of this machine is 2 tons 13 cwt. Fig. 4 illustrates a Victoria dynamo. The following figures relate to a 12-unit machine, generally known as a D_2 machine, which at 800 revolutions gives a current of 185 amperes, with an E.M.F. at terminals of 65 volts. The weight of the machine is 17cwt. 19lb. It is self-regulating for constant E.M.F. The

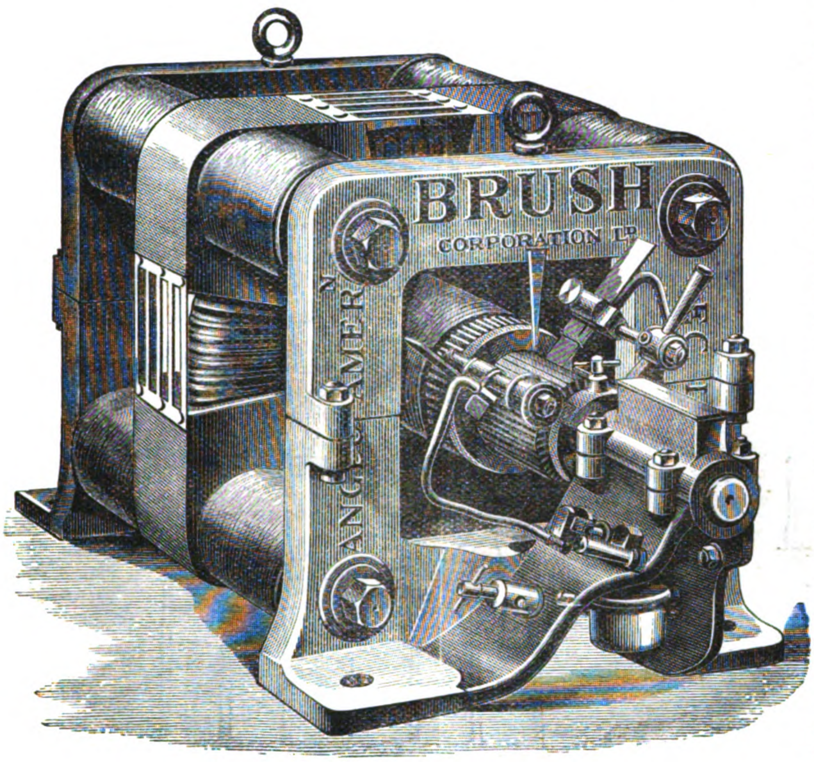

FIG. 4.—The Victoria Dynamo.

field-magnet coils have a resistance of ·002 ohm, the shunt coils of 15 ohms. The current density in the field-magnet

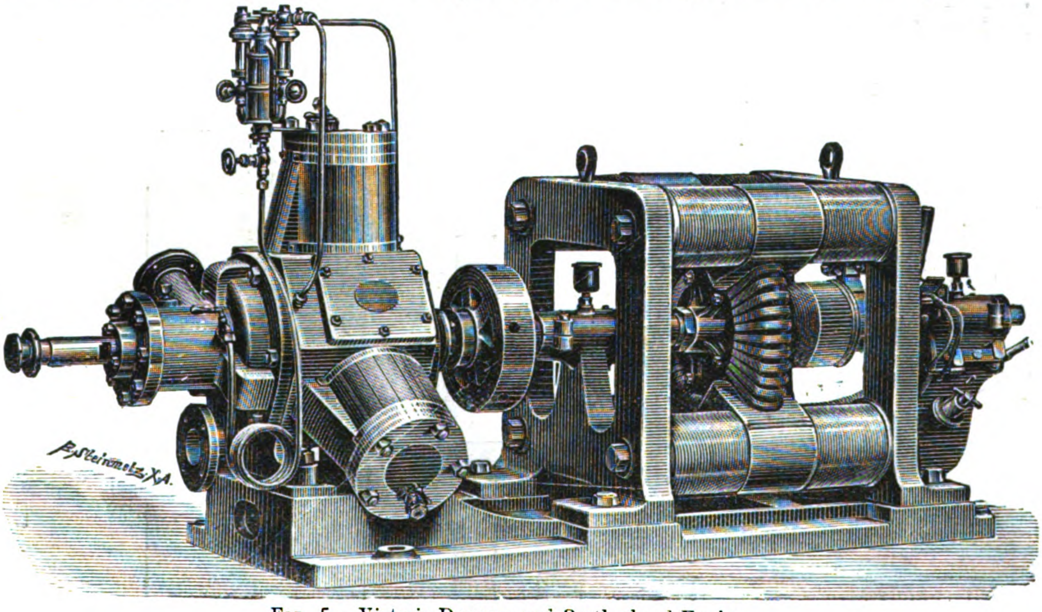

FIG. 5.—Victoria Dynamo and Brotherhood Engine.

coils is 830 amperes per square inch, and in the armature coils 2,000 amperes per square inch. Fig. 5 shows a Victoria dynamo, driven direct by a Brotherhood engine.

Messrs. R. E. CROMPTON & Co., of Mansion House-buildings, E.C., and Arc Works, Chelmsford, have also been busy during the past year in the construction of dynamos, and Fig. 6 illustrates a very large Crompton machine of a type not hitherto described. This machine has its field-magnets separately excited, and is shown in the figure coupled direct to a Willans three-cylinder engine, driving at 400 revolutions per minute. It has an output of 72 units, or 97 estimated horse-power, and absorbs 106·5 brake horse-power, showing a commercial efficiency of 91·8 per cent. The electrical efficiency is 94·5 per cent., and the total efficiency of con version is 97 per cent. At the above-mentioned speed the machine gives 600 volts at the terminals with a current of 120 amperes. The total weight of copper used is 1,400lbs., showing an output of 51·5 watts per lb. of copper. The armature is of the Gramme type, having the following dimensions:—Axial length 34in., diameter 15·5in., radial depth 3·125in. The copper on the armature weighs 287lbs., and has a total length of 915 yards, wound in 440 turns. The sectional area of the conductor is ·026in., showing a resistance between the brushes of ·23ω. The current density allowed is 2,300 amperes per square inch. The strength of the field in the armature is 17 lines per square inch, the total cross sectional area of the iron being 221 square inches, and the internal E.M.F. 631 volts. The total weight of iron used in this part of the machine is 5 cwt. The external watts per lb. of armature copper amount to 250, and the terminal volts per yard to 0·65. The clearance allowed for the armature is 0·76in., the peripheral speed is low, being only 1,620ft. per minute. The commutator has 110 parts. The bearings are 10in. in length, and are made of cast iron with white metal run in. The field-magnets are built of the best scrap iron and weigh 5 tons; and each of the four magnets measures 3ft. by 2ft. by 7½in.

The four coils are wound with 2,200 yards of wire of diameter ·237in. (sectional area ·044in.), and their resistance as connected amounts to 32ω. There are 304 turns, giving, with the full current of 36 amperes in each coil, 11,000 ampere turns, or 44,000 for the whole field.

The total watts lost in these coils amounts to 1,870, the current density allowed being 820 amperes per square inch. The over-all dimensions are, length 5ft. 9in., height 7ft. 10in., width 4ft. 0in.

LITERATURE.

A Text Book on the Steam Engine: Specially arranged for the use of Science and Art, City and Guilds of London Institute, and other Engineering Students. By Andrew Jamieson, Assoc. M.I.C.E., M.S.T.E. (London: Charles Griffin, 1886.)

We have often been asked by students to give them the name of a good text book on the steam engine, and have as often been unable to mention any one book; it has always been necessary to mention several, as equally indispensable, no single book containing all that a student requires. Prof. Jamieson's new book has very materially limited the number of books which must be mentioned in reply to such a question, and in many cases his will answer every requirement. It is difficult to say wherein lies the secret of Mr. Jamieson's success, for it is good in method, in matter, and in the selective judgment that he has displayed in dealing with practical subjects for the theoretical explanations throughout the book. For once we have a practical theoretical book.

The book consists of thirty lectures, and the author's method is first to give a description of the early steam engines and of those down to the time of Watt's latest improvement, so that the learner first gets a good notion of what a steam engine was. He then leads through thermometry and heat measurements to the use of heat for evaporating steam, keeping the student's attention close to the questions of relation between units of heat and the effects of their application. From evaporation he passes to expansion and condensation, the behaviour of steam in a steam engine cylinder, and in general the thermodynamics of the steam engine. Then he measures the power of the steam engine in various ways, and compares work actually done with the theoretical mechanical equivalent of the work represented by the heat passed to the engine or in the steam used. He then describes modern engines of various kinds, showing the difference between engines of to-day and of the time when little was known by engine makers of the direct relation between heat and mechanical effect. The various details of usual engines are described, and plenty of sections of real engines are given, though they are not all well printed. Three chapters are given on boilers of different kinds, and every chapter throughout the book is followed by a set of questions, all of which are of a practical order—that is to say they are not mere puzzles or arithmetic conundrums, but they are such as will cause the student to refer back to the chapter preceding, and by seeing the application learn to appreciate the information given him.

In dealing with questions which are often confusing to the learner, such as those relating to latent heat, to isothermal and adiabatic expansion of steam, Prof. Jamieson is very clear and concise, and it is a merit of his book that, whether descriptive or explanatory, his style is everywhere lucid without wordiness. His drawings and diagrams are well chosen, although the printer has not done justice to all. In brief his book is the best written book published for the purpose on the subject. There is nothing new in the book—the new things we expect from the men in practice—but it has the highest merits as a compilation. There are a few points to which attention may be directed as not quite in agreement with the praise we have felt compelled to bestow upon Mr. Jamieson's book.

In dealing with the indicator diagrams from a triple cylinder engine, and in reducing them to the same scale, he takes the weight of steam used per stroke in the high-pressure cylinder, and reduces this to volume of cylinder both high and low plus clearance per 1lb. weight of steam. He thus gets quantities that represent the relative lengths, *i.e.*, the volumes of the several diagrams. This is clear enough to the initiated and to the student who is helped by a lecturer, but it is not quite so clear for a student who is working by himself, as it is, at least in the first instance, necessary to know that the lengths of the respective diagrams will be proportionate to the relative volumes of the cylinders. The author remarks concerning the rise of an indicator curve above the theoretic saturation curve that this "can only be accounted for by the action of the steam jacket in re-evaporating moisture in the cylinder, or by the steam being superheated by the excessive wire drawing."

Digitized by Google

With reference to this, we may remind the author that these rises in the curves are found in diagrams from engines with unjacketed cylinders, that the rise in pressure due to jacketing, or the cessation of reduction in pressure, need not be sudden, as is usually shown by the curve; thirdly, that the cessation of reduction seems to take place more in cylinders with a somewhat early cut off and high pressure than with later cut off and moderate pressure; and, fourthly, that the cessation seems to be due to re-evaporation of steam condensed in the cylinder in the early part of the stroke partly by the heat given to the cylinder walls and piston, and partly its own heat, which comes into play with the lowering of pressure by the movement of the piston during expansion. As to the superheating by wire drawing, although the author is able to refer to the authority of some writers on this point, it is questionable whether any such superheating occurs; but if it does, it may help to explain the fact that some engines with a throttle valve are as economical as others with an automatically variable cut-off. In dealing with the effects of the inertia of the moving parts of engines the author quotes from Mr. Imray's paper before the Institution of Civil Engineers, but he might with advantage have gone to Mr. Arthur Rigg's book on the steam engine.

In his treatment of boilers of various kinds the author has not entered into the "how much," which is necessary for every student. He is not shown on what method to proceed to estimate the power of a boiler, the necessary disposition or estimation of the heating surface or the grate surface. In dealing with Cornish and Lancashire and Galloway boilers, he does not enter into the design and proportion of the flues for these boilers, and, further, he does not deal with the proportions of chimneys for these.

Having pointed out these omissions, we must conclude by mentioning that one of the most valuable features of Prof. Jamieson's book is that he not only freely mentions the sources of his information wherever it is special, but he gives the name, date, and page of his authority. These references must be of great assistance to every student who wishes to follow the subjects thoroughly, and add very much to the value of the book.

A NEW TELEPHONE TRANSMITTER.

In the accompanying engraving Fig. 1 represents a liquid transmitter, which is so wired that in its normal state the current circulates around the induction coil D with its full strength. The reason for this is that the vibrator is then nearer the screw A than the screw C. The vibrator is actuated by the diaphragm of the mouthpiece E, and its lower end enters between the points of the screws A C, the conducting liquid contained in the non-conducting vessel G. It is evident that the strength of the current passing around the induction coil will be governed by the variations of the distances of the vibrator between the screws, and which are due to the action of the diaphragm in the mouthpiece. One of the many ways of wiring the instrument is clearly shown in the engraving. Another is to connect the wire leading from the positive pole of the battery where the negative wire is shown connected, and connect the negative wire with the wire of the screw A.

FIG. I.

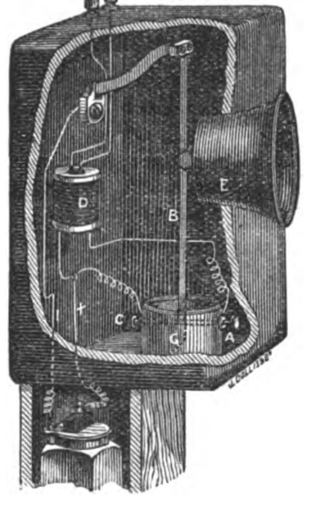

FIG. 2.

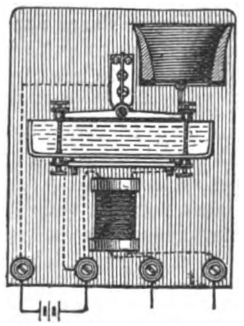

Fig. 2 shows another construction of the transmitter, in which the vibrator consists of a centrally pivoted lever, which is actuated by the diaphragm in the manner illustrated. Each end of the lever carries a screw that projects downward into the liquid, so as to face a screw passing through the bottom of the vessel. The distance between each pair of screws will thus be varied by the movement of the diaphragm, and the strength of the current passing through the coil will be regulated accordingly.

This invention has been patented by Mr. F. G. Sargent, of Graniteville, Mass.

IMPROVEMENTS IN THE BERNSTEIN SYSTEM.

On Monday, January 3rd, Mr. Bernstein invited the members of the Society of Telegraph-Engineers to a practical demonstration of recent improvements in his system of lighting. The remarks of Mr. Bernstein are given below, with illustrations of his new variable resistance plug (a most ingenious piece of apparatus) and his new switch. Most of our readers will recognise the great simplicity now attained in this system in comparison with that described in Mr. Bernstein's paper read before the Society of Telegraph-Engineers last year. Mr. Bernstein said:—

In the spring of last year I had the pleasure of reading a paper before the Society of Telegraph-Engineers and Electricians, in which I described a system of electric lighting by means of low resistance lamps. Since that time I have devoted myself exclusively to perfecting the details of this system, and to-day I am in a position to show you the system in practical operation. As I could not invite all the members of the society to come here, I limited the invitation to you, as members of the council, and I beg to express my thanks for your kind response to my invitation by your appearance here.

Allow me to enumerate in a few words the different parts of the system. We require a dynamo of high E.M.F. and producing a constant current. Conductors, which are made to carry a current of 10 amperes, and of high E.M.F. lamps for the same current, switches to turn lamps in and out, and an arrangement which prevents the interruption of the circuit in case a lamp should break—these are the essential features.

Now, as to the dynamo. Having no facilities in London at my disposal for building dynamos, I accepted an offer of Messrs. Elwell-Parker. I intended to have three sizes of dynamos built, viz., of 300 volts, 600 volts, and 1,000 volts. One of 300 volts and another of 600 volts have been finished, and of the last kind one is now in course of construction. The dynamos have Gramme armatures and commutators, and have shunt-wound magnets. The results hitherto obtained as regards constant current are very encouraging; but as they are due to the experiments of Mr. Parker I think it right to leave the publication to him.

I have given special preference to dynamos of the Gramme type over those of Brush or Thomson-Houston, because the two last machines do not produce a perfectly constant current, but rather a waving current, and are not nearly as economical in the conversion of mechanical power into electric energy as the perfected Gramme dynamo is. I have further come to the conclusion that for very long circuits it is better to connect two dynamos of 1,000 volts each in series instead of using a dynamo of 2,000 volts, and this for the following reasons:—In a system of series lighting perfection of insulation should be a primary condition. The most dangerous part of the series system rests at the dynamo, where the difference of potential reaches its maximum value. By reducing this difference of potential to one half, we reduce the danger to one quarter. 1,000 volts on each dynamo present no difficulties, and the insulation in the dynamo itself and from the ground can be made quite perfect.

None of the difficulties which are attached to the use of several dynamos in parallel exist if the connection is made in series. But there is another advantage in the use of two dynamos of 1,000 volts of the Gramme type in series, and this is the fact, that two of these dynamos are cheaper than any 2,000-volt dynamo at present in

Digitized by Google

the market. This, at first sight, appears singular, especially as we have been frequently told that it would be advantageous to build large sized dynamos, but is nevertheless a fact.

In regard to the conductors I shall have very little to say. I may be allowed to mention here that the rules published by the Phœnix Fire Office respecting conductors carrying a high tension current are exceedingly vague. They merely say that these conductors ought to be at least from six to twelve inches apart. Now, as a matter of fact, the wires leading to every one of these lamps can in this case never have more than ten volts difference of potential between them, and they are far safer by being laid quite close together than twisted wires would be in a parallel circuit, in which there is everywhere a difference of potential of 100 volts. It is quite apparent that the distance between two wires ought to be regulated by the difference of potential between them. Another point is the laying of wires inside of wooden casings. A conductor of the kind which I am using here can be treated somewhat like a gas pipe, and is in factories often less liable to be injured when exposed to view than when concealed. I was pleased to notice that the same idea seems to be gaining ground in America.

Turning now to the lamp, you will find that it has received no material alteration in appearance since the time I exhibited it to the Society of Telegraph-Engineers. As a matter of fact, the old method of making the carbon had to be abandoned on account of the decision which the Edison-Swan Company obtained in regard to the Sawyer patent, and a new method for producing a dense and hard carbon of uniform section had to be devised. The lamp has well fulfilled all my expectations. The lamps which are laid here for your inspection have been used for more than 1,000 hours, and do not show any signs of blackening. They do not now absorb any more power in proportion to the light for the production of the light than they did in the beginning. This is a very important feature if you consider that, according to the tests made by the Franklin Institute, lamps of high resistance will require almost twice as much power for production of the same amount of light as they gave at first after they had been in use for 1,000 hours.

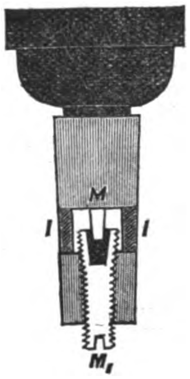

Fig. 1.—The Bernstein Variable Resistance Plug.

I now beg to call your attention to the most important and most difficult part of the series system, viz., the way of preventing interruption of the circuit in case a lamp should break. For this purpose the application of a very complictaed mechanism has always been necessary, and this mechanism was the most objectionable feature in a system of series lighting. I have been able to overcome this difficulty in the following manner:—I place two small pieces of metal in a shunt round each lamp, and separate these pieces of metal by a thin film of a metallic compound, for instance, oxide of mercury mixed with carbon powder. If the lamp is in proper condition, an exceedingly small current will pass through this mixture, which has a resistance of about 500 ohms; but if a lamp gives out, its resistance increases very rapidly and a larger current will pass through the shunt. The larger current now produces such local heat in the film of oxide of mercury that an instantaneous reduction of the oxide takes place, and a certain amount of metallic mercury is formed. A free passage of low resistance for the whole current is thereby produced, and an interruption of the circuit is impossible. This apparatus, which is made in the form of a small cone (Fig. 1), is arranged to fit into the switch, as I shall describe later on. In Fig 1, MM_1 shows the metallic connections, II. the insulating medium. The black part is the oxide of mercury and carbon dust. The screw M is used to obtain the necessary resistance by increasing or decreasing the pressure. I shall now demonstrate the action of these contacts by first connecting one with a single lamp, in which case they have no effect whatever on the light of the lamp, and afterwards connect the same contact with a large number of lamps, or disconnect the wires from the lamps entirely, and you will find that the contact acts in the way I have described. [Experiment performed.]

These contacts play a similar part in the series system which the fusible wires do in the parallel system, but the latter break the circuit in case the current becomes too strong, and the former make a circuit under the same condition. I think the contact is an interesting example of the replacement of a complicated mechanical apparatus by a very simple chemical action. It follows from the action of the contact that it has to be replaced after it has once acted, but as there is nothing used up except the metallic compound, the renewal of the contact is done at a mere nominal expense.

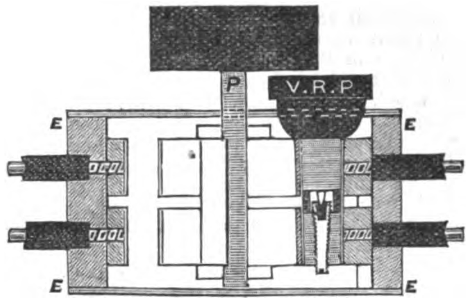

Fig. 2.—Bernstein Double-Pole Short-Circuiting Switch.

I shall now lastly describe the switch (Figs. 2 and 3) which I have designed for this system. It may be briefly specified as a double-pole short-circuiting switch. All the working parts of the switch are fastened to the inside of a small ebonite cylinder, closed at each end, so that contact from the outside with any part conveying a current is impossible. There are four segments fastened on the inside of this cylinder, two of which receive the line wires, and the two others the lamp wires. A central pin, P, which is insulated from all the working parts, carries an ebonite handle outside the box, and two metal pieces inside, which in a certain position of the handle connect the line wires with the lamp wires. If the handle makes one quarter turn these two metal pieces rest on insulation, but before this can take place another piece of metal connects the two line wires, thereby producing a short circuit of the line inside the switch. Two metal bosses, provided with a taper hole, are connected with the segment which carries the lamp wires. The contact plug fits into this hole, and if put in forms a shunt of high resistance to the lamp. The arrangement of the handle and the contact plug is made in such a manner that the current must be short-circuited before the contact can be removed; and it is further arranged that the contact must be put in its place in order to obtain a light in the lamp. This last has been done in order to prevent people from using a lamp without protection of the circuit by means of the contact.

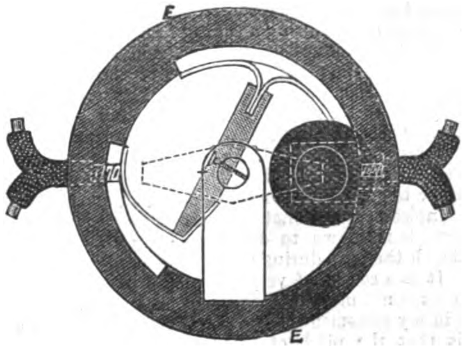

Fig. 3.—Plan of Switch.

Allow me now to add a few words in regard to the practical use of the system. A small experimental plant has been in operation in the alkali works of Messrs. Brunner, Mond and Co., at Northwich, the light having been kept constantly running from four o'clock in the afternoon till eight o'clock next morning, since the middle of October last year. Not the slightest hitch has occurred since starting the plant, and there has been no cessation of the lighting during the specified time, even for one minute, although the plant is superintended by an engineer who never had anything to do with electric light before. I think this speaks well for the security and simplicity of the system. Another plant was started in our own factory about the same time, the light being kept running every day from morning to night. A third plant has lately been put in operation for lighting the cooperage at the above-mentioned alkali works, and a fourth plant will be started next week for lighting the saw mills of Messrs. G. Smith and Co., on these premises. I hope that these demonstrations, and the facts laid before you, may have proved that my labours in this direction have not been in vain.

A NEW THEORY ON THE SENSE OF HEARING.

At the Birmingham Meeting of the British Association a lecture was delivered by Dr. William Rutherford, M.D., F.R.S., on "The Sense of Hearing," from which we take the following highly interesting passage :—

Some five years ago it struck me that the case of the telephone may throw light on these difficulties regarding the sense of hearing. In the telephone there is a thin plate of iron placed near the end of a permanent steel magnet. A bobbin of thin copper wire is coiled round the end of the magnet nearest the plate, and is connected with a bobbin of wire around the magnet of a second telephone in every respect similar to the first. When sound waves fall on the plate of the transmitting telephone it vibrates. The vibrations of the iron near the magnet affect the magnetism, and so induce in the wire currents of electricity whose frequency and amplitude correspond to those of the vibrations of the iron plate induced by the sound. The currents travel to the receiving telephone and induce oscillations of its magnetism, which in turn cause its iron plate to vibrate and produce sounds similar to those communicated to the first telephone. These is no analysis of the sound waves. The transmitting telephone takes up simple or complex vibrations The harmonies of an orchestra may fall upon it, and it does not fail to convert the complex sound vibrations into electrical vibrations, and these again into the complex sound of the orchestra in the receiving telephone. It is, indeed, one of the most wonderful inventions of recent times. Can it throw light on the sense of hearing?

The theory which I have to propose may be termed the Telephone Theory of the Sense of Hearing. The theory is that the cochlea does not act on the principle of sympathetic vibration, but that the hairs of all its auditory cells vibrate to every tone, just as the drum of the ear does; that there is no analysis of complex vibrations in the cochlea or elsewhere in the peripheral mechanism of the ear; that the hair cells transform sound vibrations into nerve vibrations similar in frequency and amplitude to the sound vibrations; that simple and complex vibrations of nerve molecules arrive in the sensory cells of the brain, and there produce, not sound again, of course, but the sensations of sound, the nature of which depends not upon the stimulation of different sensory cells, but on the frequency, amplitude, and form of the vibrations coming into the cells, probably through all the fibres of the auditory nerve. On such a theory the physical cause of harmony and discord is carried into the brain, and the mathematical principles of acoustics find an entrance into the obscure region of consciousness. Now, if nerve energy were only electricity, that theory would probably be accepted at once. But nerve motion is very sluggish when compared with electricity.

I have kept this theory back for five years, because I felt I had no evidence of the possibility of sending a rapid succession of vibrations along a nerve. It cost me a good deal of thought and experimental observation to find the evidence I required. If we give to a motor nerve of a frog or rabbit ten instantaneous shocks of induced electricity in a second, ten impulses will pass along the nerve to the muscle, and produce ten distinct contractions in the same period. If we send forty impulses along the nerve, we get, not forty contractions of the muscle, but a single continuous contraction, because the several contractions are fused together. Now, if we listen to the muscle so stimulated, we hear a musical note having the pitch of forty vibrations per second. Each sound-vibration results from the sudden shock of chemical discharge due to the arrival of each nerve impulse in the muscular substance. If we stimulate the nerve, say, 200 times per second, by causing a tuning-fork to make and break the primary circuit of an induction machine, and so send 200 shocks per second into the nerve, the pitch of the note in the muscle exactly corresponds. It has the same pitch as the fork. I experimented in this way, and eventually found that I could send as many as 352 impulses per second along the nerve of a rabbit and get a note from the muscle of the pitch of 352 vibrations per second—that is, a note of the pitch of F in the lowest space of the treble clef. But when I tried by more rapid stimulation of the nerve to get a higher note from the muscle, I failed; there was nothing but a noise heard. That a low rumbling sound is produced by a contracting muscle is known to every physiologist. You can hear it if you firmly clench the jaws during the stillness of night, when other sounds are hushed. It is a sound of very low pitch due to vibrations certainly below 40—perhaps not more than 10 or 12 per second. There is therefore nothing new in my statement that a note may be heard in a muscle; the new point is that the pitch of the note may be increased by a more rapid stimulation of the nerve, and that as many as 352 impulses may be sent along a nerve and retain their individuality so sharply that they can produce a note in a muscle having a pitch number of 352. That fact will give support to a vibrational theory of nerve energy.

Now, am I to conclude that, because I failed to get a higher note than one of 352 vibrations from the muscle, it is not possible to send more than 352 vibrations per second along a nerve? By no means; the fibres of a muscle are very different from those of a nerve, and also very different from nerve cells. The molecules in both of them can probably vibrate far more rapidly than 352 times per second.

I have, therefore, directly proved that vibrations of the same frequency as all the lower tones of the scale, from the lower F of the treble clef downwards, can be transmitted by a nerve. A short time ago it occurred to me that the note produced by the wing of an insect furnishes a simpler proof of the possibility of transmitting a rapid series of impulses along a nerve. The wing of the humble bee produces the note F in the lowest space of the treble clef. It gives, therefore, 352 complete vibrations in a second. Every downward motion of the wing doubtless results from an impulse sent along the nerve to the muscle that lowers the wing. Therefore we may conclude that about 352 impulses per second traversed the motor nerves of the humble bee's wing during flight. In the honey bee the note of the wing is A in the treble clef—that is, two notes higher than in the humble bee, so that 460 impulses appear to pass along its motor nerves in a second. In a human motor nerve the impulses transmitted by it during voluntary effort are not more than 10 or 12 per second (Schaefer). I have, therefore, some substantial evidence in support of my theory of sound sensation. And I cannot but think that the evidence in favour of it will increase. I do not wish you to suppose that on my theory of hearing difficulties disappear. Far from it. I merely assert that the difficulties which seem insurmountable on the theory of Helmholtz are diminished by the theory which I have submitted. Should my theory of the sense of hearing find acceptance, it will lead to a reconstitution of theories regarding the other sense organs.

BUSINESS NOTE.—We understand that Mr. Henry Edmunds has become a partner in the firm of Walter T. Glover and Co., the electrical wire and cable makers of Salford, Manchester. The firm have taken new London offices, at No. 10, Hatton-garden, E.C. Mr. Edmunds will continue to reside in London.

NOTES.

Reported Illness of Edison.—A Philadelphia telegram in *The Times* states that Mr. T. A. Edison is lying seriously ill.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended January 7th amounted to £3,477.

The West Coast of America Telegraph Company.—The directors of this company have declared an interim dividend of 2s. per share.

Electric Lighting Tender Wanted.—Messrs. Foster Brothers, of 254—256, Coventry-road, Birmingham, invite tenders for the supply of plant, including engine, for lighting their premises by electricity.

The Commercial Cable Company.—This company last week completed the second year of its existence, upon which occasion each of the *employés* was presented by Mr. Mackay with one half of a month's salary.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending January 7th were £2,762, after deducting the fifth of the gross receipts payable to The London Platino Brazilian Telegraph Co.

Telephone Telegrams in Belgium.—The last return of the number of telegrams delivered by telephone in Belgium is at the rate of nearly half a million per annum. This probably implies a substantial saving in the wages of telegraph messengers in the larger towns.

"Munro and Jamieson's Pocket Book of Electrical Rules and Tables."—We have received a copy of the fourth edition of this well-known work, to which further additions have been made. The book is published by Messrs. Charles Griffin and Co., of Exeter-street, Strand.

American Electrical Patents.—The United States Patent Office has prepared a reprint of patents relating to electricity issued up to July 1, 1881. The specifications are arranged under sixty-nine sub headings, and fill sixteen quarto volumes of 2,000 pages each. The price is $454.

The Edison System in France.—A project has been set on foot for the amalgamation of the three companies which are engaged in the "exploitation" of the Edison system in France. These are the "Continental Edison Co.," the "Société Electrique," and the "Société Industrielle et Commerciale Edison."

The Direct United States Cable Company.—At the board meeting on January 7 it was resolved to pay an interim dividend of 2s. per share, free of income-tax, being at the rate of 2 per cent. per annum, for the quarter ending 31st December, 1886, such dividend to be payable on and after the 22nd inst.

The Colonial Conference.—The Colonial Conference on Postal and Telegraphic Communications will be opened in London on 1st April next. The colony of Victoria will be represented by the Hon. James Lorrimer and the Hon. Alfred Deakin. New Zealand will be represented by Sir Francis Dillon Bell.

La Société Générale des Telephones.—At the close of 1886 the French Telephone Company had reached a total of 6,890 subscribers, of which 111 were connected during the month of December. A new telephone company is about to be established in France to work micro-telephones patented by M. C. Herz.

Submarine Cables Trust.—Notice is given by this trust that the balance of ten shillings left outstanding on the coupon of October 15th, 1886, will be paid on and after the 15th inst., by Messrs. Glyn, Mills, and Co., of Lombard-street, between the hours of 10 a.m. and 2 p.m. The coupons must be left with the bankers five clear days previously to calling for payment.

Electric Railway in Austria.—In addition to the scheme for an electric railway at Buda-Pesth, which we recently described, the Austrian Minister of Commerce has granted a concession to the firm of Siemens and Halske for the construction of an electric railway from Salzburg to Lend, and thence to Wilbad-Galstein. It is intended eventually to prolong the line to Bockstein.

Temporary Lighting.—The Tradesmen's Association of Batley instructed Messrs. Goolden and Trotter, of Halifax, to illuminate the principal thoroughfares of their town on Christmas Eve and the preceding evening. The lighting was carried out with complete success by eleven arcs, on a circuit of rather more than a mile in length, and, we believe, had the desired effect of assisting a brisk Christmas business.

Cockermouth.—The Town Council of this town, at several of their recent meetings, have had under their discussion the question of asking for tenders for lighting the streets of the town by electricity by means of power derived from the River Wear. No definite conclusion has been arrived at, but the council are still open to suggestions upon the subject.—The National Telephone Company are about to extend their system to Cockermouth.

An American Suggestion for Solving the Wire Problem.—Col. Flad, President of the Board of Public Improvements of St. Louis, proposes the erection of iron towers 100ft. to 150ft. high at the street corners to carry all overhead wires. The towers are to rest upon four arched supports meeting at a height of 40ft. or 50ft. over the centre of the roadway. Arc lamps to be suspended from the centre of the arch, and all wires to range perpendicularly at various levels.

Tenders Required for Electric Lighting in Spain.—The Municipality of Lorca, a town of 50,000 inhabitants in the south of Spain, invites tenders for electric lighting under conditions favourable to the contractor. A monopoly of fifty years is guaranteed, and the town itself will pay £720 per annum for 260 20 candle-power lamps, while private lighting may be undertaken on such terms as the contractor thinks fit to offer. Further particulars may be obtained on application to the municipality.

The Lighting of Rome.—Messrs. Ganz and Co., of Buda-Pesth, write to inform us that the alternating current machines and transformers for the extensive installation which is about to be carried out by the Anglo-Roman Gas Company will be supplied by them, the transformers being of the well-known Zipernowski-Deri-Blathy type. Messrs. Ganz and Co. have carried out central lighting stations upon this principle in the following towns up to date:—Milan, Turin, Bogni di Lucca, Treviso, Lucerne, Gerona, and Montevideo.

The Society of Arts.—The last Wednesday evening lecture at the Society of Arts was delivered by Prof. Reinold, F.R.S., who gave the second of his two juvenile lectures on "Soap Bubbles." Among many other experiments of great interest and beauty was one which consisted in sending a current of electricity up or down a soap film. It was shown that a fluid current was set up in the film corresponding with the nominal direction of the electric current, so that the film became rapidly thinner near the electrode at which the current entered.

The Austrian Telephone Company.—Messrs. F. C. Stoop and Co. write us as follows:—"The Telephone Company of Austria has been more fortunate than the London company, as you will perceive by the following extract from a letter from

Digitized by Google

the manager :—'We have had heavy snowstorms, but happily up to now no damage worth mentioning ; all that was done was to throw some trees on some of our pole lines in Bielitz, breaking about ten wooden poles, which were replaced in a day.' The company have now 1,700 subscribers to its exchanges in Austria."

A State Electrical Laboratory for France.—The French Government has decided to establish "a central laboratory of electricity," under the direction of the Minister of Posts and Telegraphs. M. de Nerville has received the appointment of director of the new institution, although nothing has yet been decided as to the exact organisation and functions of the establishment. It is, however, probable that the verification and calibration of electrical instruments will form the chief part of the work undertaken, and it is hoped that a department for special research will also be included. A commission is to be appointed to determine these matters.

The South of England Telephone Company.—We are now able to supplement the details which we gave in our last issue respecting the work of this company by the following complete list of the exchanges which they have now in operation :—

Company's Exchanges.	Lines to Exchange.	Company's Exchanges.	Lines to Exchanges.
Brighton	282	Dover	23
Hastings	77	Maidstone	16
Eastbourne	55	Northampton and Wellinboro'	89
Norwich	76	Cambridge	120
Ipswich	70	Oxford	28
Great Yarmouth	11	Reading	60
King's Lynn	18	Bedford	18
Chatham	24	Luton	37
Folkestone	28		

The Zanni Incandescent Filament.—The *Chronique Industrielle* states that the Zanni filament is made by the following process :—Ground carbon is mixed with gas tar so as to form a stiff paste, and is then placed in a metallic cylinder, having at one end a small hole, the diameter of the required filament. The material is then forced through this hole under strong pressure. The threads thus formed are cut up into suitable lengths, and raised to a white heat in a closed muffle. This leaves the filament in a porous condition. The material is then dipped in a solution of platinum chloride, or of calcic chloride, and again raised to a high temperature, when it is found to have assumed a solid structure. We believe that the lamps made by this process possess some good qualities, but it seems unlikely that the filaments will possess that homogeneous structure which is usually considered so desirable for lamp filaments.

A New Double Current Key for Cable Signalling. At the last meeting of the Société Internationale des Electriciens, M. L. Maiche exhibited a new double current key designed more particularly for use with the siphon recorder. Instead of a single set of contacts, as in the usual Morse signalling key, the new key has two sets of contacts, and is manipulated like a pair of single-needle pedals. The depression of the right hand key, however, transmits dashes, and that of the left hand dots, each followed by reverse currents as in the ordinary double contact key ; but by means of a mechanical attachment these reverse currents are sent after a definite interval, and for a definite period, which is independent of the actual period of depression. This is accomplished by causing the depression of each key to liberate an excentric, which is then driven forward by clockwork, and closes the circuit for the required interval in either direction. This would seem to be a substantial improvement in cable signalling apparatus.

Magnetic Insulation.—According to an American journal, a Boston scientist, who has spent the last 50 years of his life in searching for a substance which should be impermeable to magnetic lines of force, has been at length successful in the discovery of a metallic compound capable of playing the part of a perfect magnetic insulator. Although for our own part—and to put it bluntly—we attach not the slightest importance to this story as it comes to us at present, yet we are not aware of any valid reason for denying the possibility of the existence of such a substance as is here suggested. It is true that up to the present time we have no authentic record of the existence of any body whose magnetic permeability is perceptibly less than that of air, but nevertheless we do not think that in the present state of our knowledge the search for a magnetic insulator should be placed in the same category as the quest of the Philosopher's Stone or for the Elixir Vitæ. Apart from the many obvious uses for a material possessing this property, we have recently been shown a scheme which promises to revolutionise the face of the earth—so far as matters electrical are concerned—if only a magnetic insulator be forthcoming.

Halifax.—At the last meeting of the Halifax Town Council the Town Clerk read a communication from Mr. Hugh Watt, Chairman of the Maxim-Weston Electric Company, with respect to electric lighting in the borough. The letter pointed out that in the case of the Town Hall and other public buildings, a great saving would necessarily accrue in the non-destruction of decorations, painting, &c. If the Council were desirous of adopting the light the company would lay down a plant consisting of 1,000 lamps, each of 20 candle-power, including dynamos, cable, leads, labour, electrical sundries, steam engines, and all necessaries, for £3,000, provided the Council saw their way to purchase the plant out and out ; and he would be willing to maintain this at an annual cost of, say, £700 a year, although he thought after the first twelve months the Corporation would find it much cheaper to maintain the plant themselves. As to the question of rental, if the Council would place in the hands of the company an order for, say, a thousand lamps, these should be laid down, ¾d. per lamp per hour being charged for the minimum number of hours during which the lamps had to run during the year. The letter was referred to the Lighting Committee.

Hall's Phenomenon in Gases.—Professor Boltzmann has recently detected the existence of Hall's phenomenon in gases, the rotation of the equi-potential lines for carbon, di-oxide, hydrogen, and air being in the same direction as for gold. The experiment was made by means of a Geissler tube of rhomboidal section in which the gases were exhausted to the pressure of 2·5mm. The current from the induction coil entered and left the tube at the acute angles of the rhumboid, and two separate platinum electrodes inserted at the obtuse angles were connected with a very sensitive galvanometer. When the tube was placed in a uniform magnetic field such that the lines of force were perpendicular at the same time to the direction of the current in the tube and to the line connecting the secondary electrodes, a current was set up in the circuit of the latter, which, as already stated, was in the same direction as in Hall's experiment with gold leaf. Professor Boltzmann also took two similar Geissler tubes connected in parallel, so that the current divided itself nearly equally between them. If a magnetic field directed perpendicularly to the current were then set up in one tube, the current in this tube was observed to diminish to one-tenth of that in the other.

The Thermo-Electric Properties of Electrolytes.—In *Wiedmann's Annalen*, M. Donle gives the results of some

Digitized by Google

experiments which he has carried out upon the above subject. The following are the conclusions at which he has arrived :—(1) The thermo-electric force of the combination of two electrolytes increases with the difference of temperature of the contacts; (2) The differences of potential increase in general less quickly than the differences of temperature; (3) The degree of concentration of the solutions has not much influence; (4) But the thermo-electric force increases in general when the concentration of one of the solutions diminishes; (5) In the combination of a sulphate and a chloride of the same metal, the sulphate forms the positive pole; the current passes, at the warm contact, from the chloride to the sulphate; (6) In general, the sense of the thermo-electric force is the same as that of the contact electromotive force; (7) The sense of the thermo-electric force between two salts of the same acid is the same as the electromotive force of contact for the corresponding metals. These observations have an important bearing upon various questions connected with the rational theory of chemical reactions, which is now being built up from the study of thermo-chemistry, as well as upon the intricate question of the seat of the electromotive force in the voltaic cell.

THE LATE SIR FRANCIS BOLTON.—Colonel Sir Francis Bolton was buried on Tuesday, the 11th inst., at the cemetery, Hastings, where his mother's remains lie interred. Amongst the mourners were his brother, Mr. M. W. Bolton; his cousin, Colonel Braham; his partner, Mr. P. A. Scratchley, M.A.; his solicitor, Mr. G. A. Gadsden, Mr. Thomas Bond, F.R.C.S., Mr. J. H. Francis, C.E., engineer to the New River Company; Mr. M. W. Morris, C.E., engineer to the Kent Water Works; Mr. W. E. B. Farnham, Mr. F. E. Lewis, Mr. J. D. A. Norris, Dr. Winter Fisher, Mr. H. Bird, and Mr. H. Richards. The Society of Telegraph-Engineers and Electricians was represented by two of its past Presidents, viz., Major-General Webber, C.B., late R.E. (who, with the late Mr. R. Sabine and Sir Francis, founded the society), and Mr. W. H. Preece, F.R.S. (who had been intimately connected with Sir Francis in connection with the electric lighting of the recent International Exhibitions at South Kensington), and Mr. F. H. Webb, the Secretary. Many other members of the council would have attended but for important engagements which prevented them going so far as Hastings. Mr. James Sivewright, C.M.G., travelled up from Greenock on Monday night in order to be present, but in consequence of the train being delayed reached London too late on Tuesday morning to enable him to catch the Hastings train. Sir Francis's staff was represented by Messrs. D. Urquhart, Mr. W. Bates, and Mr. R. Loam.

MR. QUARRIE'S SYSTEM OF GENERATING ELECTRICITY.—We have received from Mr. Quarrie a letter in which he is good enough to assure us that his knowledge of electrical matters "is not of that technical, abstruse, mystified, tissue of mathematical puzzles and their tangled solution, represented by the accepted scientific treatment of electricity." Mr. Quarrie's method is, on the contrary, sufficiently simple. It consists of "taking a few accepted facts, and applying the same." The only difficulty, as it seems to us, that can arise in the application of this method, is that of knowing just how many facts it is desirable to take account of, and how many may safely be left out of the reckoning. The possession of this system has, however, led Mr. Quarrie to the brilliant conception of seizing on any and every suitable occasion upon which something happens to be in motion, and attaching thereto in some manner—the details are not clearly explained—an apparatus which may perhaps be roughly described as a dynamo-armature. Thus there is no longer any need for "even the ghost of a special engine" in order to obtain "an abundant supply of electric light." How wonderfully simple! and how pleasing it is to be assured by Mr. Quarrie that he *knows* that in the end his results will astonish those arrogant persons who have hitherto "thought that they only knew anything of electric matters." Our readers must please note, however, that Mr. Quarrie has applied for, and has received, Her Majesty's letters patent for this system.

THE SCHOOL OF ELECTRICAL ENGINEERING, HANOVER-SQUARE, W.—After the Christmas examination for the final vellum certificate of this school, a very satisfactory report was received by the managers, Messrs. W. Lant Carpenter and L. Drugman, from the external examiner in the electrical subjects, Mr. H. R. Kempe, of the Engineer-in-Chief's Office, G.P.O. Out of 18 students who presented themselves from the class of the senior instructor, Mr. H. D. Wilkinson, the certificate was awarded to eight, whose *average* percentage of full marks was 91 per cent. in the theoretical questions, and 95 per cent. in the practical ones. No certificate is awarded for less than 70 per cent. in each case. The names and marks percentages of the successful students in electric lighting and power transmission are—A. G. Sanders, 99·3; A. E. Levin, 98·0; C. Mott, 94·7; W. L. Copp, 93·3; F. A. Harris, 92·0; W. F. Collins, 91·3; E. Payne, 81·3; in electric and submarine telegraphy and telephony, B. Brown, 87·3. The first seven students having previously passed the examination in the course of lectures on mechanical engineering receive the full certificate of the school, which, we may add, now numbers 55 pupils. A steam engine will very shortly be placed in the machine room to replace the gas engine at present in use. We are also informed that arrangements have just been completed, whereby, in addition to the course of practical instruction in the school itself, advanced students will have the opportunity of gaining actual experience by spending a portion of their time in the workshops of Messrs. Swete and Main, electrical engineers, Kensal-road, W.

"LES TELEPHONES USUELS."—We have received from MM. J. Lebèque et Cie, of Brussels and Paris, a copy of "Les Telephones Usuels," by M. Charles Mourlon. This is a work of some three hundred pages, profusely illustrated, and containing elaborate descriptions of a very large number of modifications of the original Bell Telephone, some good, some bad, the majority probably indifferent. Given a magnet of indeterminate shape, one or more helices of indefinite dimensions, and some structure which fulfils the not very onerous condition of coming within the legal definition of a diaphragm, and it is obviously possible to construct an indefinite series of instruments more or less capable of fulfilling the purposes of a telephone receiver. Observations of a similar character will apply to the transmitters, which are also extensively represented in these pages. It has been a matter for surprise to us to learn what a large number of gentlemen of French and Belgian nationality have occupied their leisure in ringing the changes on this gamut. We turned with greater interest to Chapter IV., on "Bureaux Centraux," hoping to find some detailed information on a subject on which much remains to be said. The information which is given upon this head is, so far as it goes, of a valuable character, and the illustrations are well and clearly drawn; but the information is by no means brought up to date, and several improvements of American origin are entirely omitted. The book is one which in other respects deals in a satisfactory manner with the subjects taken up, and which include batteries, insulators, lines, call-bells, and other subsidiary apparatus. But we are still of opinion that the standard treatise on telephony remains to be written.

LIGHTNING PROTECTORS FOR TELEGRAPH AND TELEPHONE CIRCUITS.—In a paper upon the above subject by M. F. Van

Digitized by Google

Rysselberghe, which appears in the *Bulletin de la Société Belge d'Electriciens*, the author divides lightning protectors into the following classes :—(1) Fusible wire protectors. (2) Protectors based upon the discharging effects of points, and consisting usually of two opposed plates of metal studded with numerous points. (3) Protectors in which the discharge is effected in a vacuum by means of Geissler tubes. (4) Protectors in the form of condensers, consisting merely of two metallic plates separated either by an air-space or by a thin sheet of paper. M. Rysselberghe then describes a series of experiments which he has undertaken in order to determine which of these forms is the most effective. He has been led to the conclusion that the protectors classed under the third division are the most generally useful. Nevertheless, an extended experience of the fourth class, in which reliance is placed upon a simple condenser with a paper dielectric, has shown that this form is equally effective in action. More than 2,000 such protectors are in use in Belgium, and although last year was an exceptionally stormy period only two actual failures are reported. The objection to the system, however, arises from the fact that after any very energetic discharge not only is the dielectric pierced but the line is frequently put to earth. This, says M. Rysselberghe, is not a serious inconvenience when the protector is placed in a telegraph office, where matters can immediately be restored to their normal condition, but it renders the type unsuited for use with telephonic apparatus. For the latter purpose, therefore, M. Rysselberge prefers to use a Geissler tube protector with electrodes of nickel.

With all Humility.—We are sure that our readers will share with us the concern which we feel on learning that a proposal recently put forth in these columns has "made *The Electrician* ridiculous in the eyes of all France." So at least we are assured by one of our contemporaries across the Channel; and as if this were not in itself a sufficiently overwhelming announcement, our merciless critic proceeds to indulge in the most cutting observations at our expense, likening us (as we fear sarcastically) to Solomon the Wise, and parodying our unhappy suggestion with the most lively ingenuity. Our readers will be anxious to know in what particular we have offended. It was in a note on the centenary of Arago (*The Electrician*, Dec. 17th, page 117). We there ventured to make this suggestion :—That inasmuch as a certain troublesome phenomenon, usually known under the name of Foucault, had first been observed by Arago and elucidated by Faraday, it might, with some propriety, be called the "Farrago." *Mais, si vous plait* M. le redacteur de *l'Ingenieur Electricien*, really this was only our fun; it was not due, as you are pleased to say, to our "ridiculous love of neologism" (!) but rather, in point of fact, to our neologistic weakness for the (occasional) ridiculous. We are well aware, however, that this is a very paltry excuse, and much trouble might have been avoided had we been content to follow the classic example of Artemus Ward, and written "N.B.—This is a goak." Our sapient critic proceeds to parody our ideas by suggesting that the ohm be henceforth called the "ohmlette"—a witticism which is in itself a demonstration of the superior sprightliness of the Gallic wit, with which, for our own part, we recognise the hopelessness of all further attempts to compete.

Electric Lighting of Collieries.—Mr. Charles Lever, writing to *The Times* on this subject, says :—"I have urged in your columns on many occasions the use of only the best lamps, and the prohibition of the use of gunpowder for blasting in coal mines. I have offered rewards for the best lamps—electrical and otherwise—and for a perfectly safe substitute for gunpowder. The latter is now an accomplished fact, and coal can now be safely blasted in the most fiery seam without fear of explosion. The lamp question may not yet be finally solved, but Mr. J. Wilson Swan, M.A., spent an evening at my house a few weeks ago, and I was delighted to see that he had invented an electrical, portable, safety lamp, burning in vacuum, giving an excellent light, and with a fire-damp indicator attached. This lamp—Mr. Swan's latest invention—I believe to be absolutely safe. Other effective and safe electrical lamps have been sent to me for inspection and experiment. These are 'as light is to darkness' compared with the dim glimmer of the old safety lamp still in use. Last month I had a long conversation with Sir Frederick Abel, the greatest authority of the present day on explosives, who was the leading scientific member of the Royal Commission on Accidents in Mines, and he is entirely of my opinion that the time is very near to us when the dark recesses of our coal mines will be brilliantly illuminated by means of perfectly safe, efficient, portable, and (in the best sense) economical electrical lamps. When this happy time arrives explosions will be rare, and the deaths from falls of roofs or sides of the workings, and other casualties which carry off the miners one by one will cease or be reduced to a minimum. I firmly believe that instead of 1,200 deaths in coal mines annually we shall not exceed 200, and instead of 90,000 miners, being injured every year the number may be reduced to less than 10,000. The better light afforded to the miners the greater their degree of safety. Darkness and danger are akin, and in coal mines especially frequently mean death."

A Thermo-Electric Study of the Phenomenon of Recalescence.—The term recalescence refers to the singular phenomenon of spontaneous re-heating which occurs during the cooling of cast iron or steel. This can best be seen by raising to a red heat a thin piece of iron or steel such as a needle. It may then be noticed that just as the red heat has died away there is a sudden return or rebound of the temperature, so that the iron again flashes into momentary redness. M. Osmond has recently undertaken the investigation of this subject by a thermo-electric method, in the laboratory of the Ecole des Mines at Paris. The particular object aimed at was to determine whether recalescence is due to the liberation of heat, owing to a modification of the molecular structure of the iron, or whether it is due to a chemical action upon the carbon. A thermo-electric couple, consisting of platinum and platinum-rhodium alloy was employed, with a d'Arsonval galvanometer. The curves of temperatures for various specimens of cast iron and steel of different hardnesses were examined during the period of cooling from a temperature of 800°. The amount of carbon present in the iron was 0·16 per cent. and in the steel it varied between 0·57 and 1·25 per cent. The following facts were ascertained as the result of the experiments :—(1) The temperature of recalescence rises when the amount of carbon is increased and the temperature of transformation of the iron falls, until in hard steel these two temperatures are coincident. (2) The rapidity with which heat is applied within the range of 1° in from two to ten seconds has no influence upon the critical points. (3) The critical points are a little lowered when we raise the initial temperature from which the cooling takes places from 736° to 840°. (4) The critical points lower themselves below the point of visibility when the first cooling is conducted with rapidity, as in the process of tempering. (5) During the annealing after tempering, the latent heat of tempering (?) is disengaged progressively and not suddenly. The author is of opinion that this method of studying iron and steel is likely to lead to important practical processes for determining the qualities of iron.

THE PARIS BRUSSELS TELEPHONE LINE.—This line has now been completed throughout, and communication between the terminal stations has been successfully established. Before, however, the full advantage of the scheme can be realised in through communication between the subscribers to the local exchanges in the two cities, there remains a further problem to be solved. The Paris subscribers have the good fortune to enjoy complete metallic circuit communication, and no difficulty arises in placing them upon the trunk line. But at Brussels, where an earth circuit is in use, some form of relay or repeater becomes necessary before this connection can be made. Nothing has yet been decided in this matter, and although several forms of telephone repeaters have been devised, we are not aware that any definite success has been attained with such instruments up to the present time; and we shall therefore watch the development of the complete scheme with considerable interest. The Exhibition of Telephony, which is now open in Brussels, will not improbably be the means of providing a solution of the problem. It will be remembered that it was at one time proposed by the Belgian authorities to attempt to make use of the Van Rysselberghe system upon this line, and they even wished to employ a pair of previously existing iron wires. The French very naturally demurred to this, and in the end a pair of phosphor bronze wires were erected upon the same posts, the wires being crossed upon the method first employed by the English Post Office. These wires have a diameter of 3mm. and weigh 65 kilogrammes to the kilometre (say, 227lb. per mile), with a conductivity of 95 per cent. The total length of the line is 315 kilometres, and the resistance of each wire is 2·4 ohms per kilometre, or a total resistance of 1,512 ohms. The total cost of the line, excluding posts, amounted to 85,000fr. Now that the line itself has been built to meet the exigencies of telephonic, rather than telegraphic, communication, the question of employing it for the latter purpose also by means of the Von Rysselberghe system assumes a different aspect, and this, we believe, will shortly be done. The tariff has been fixed at three francs for five minutes' conversation.

A SAD FATALITY.—We very much regret to record a sad accident which took place in connection with the extensive installation of the Grosvenor Gallery Electric Supply Company. The circumstances are surrounded with some degree of mystery, if the evidence tendered at the inquest is to be implicitly received. One thing, however, is rendered certain, both by the medical evidence and the verdict of the jury—namely, that the death of the unfortunate victim was not due to an electric shock, but was caused by a fall from the roof of the premises. The evidence given at the inquest was as follows:—"Mr. Mortimer Davis, a tobacconist, carrying on business at 84, Regent-street, deposed that the deceased was his errand boy. On the 3rd instant witness was returning home to dinner at half-past six, and on passing the premises of Messrs. Gerrard and Co., florists, which adjoin his own, he noticed that the electric light was out, and some one was lighting the gas. Witness went indoors and was met by an overpowering smell of burning varnish and wood. Almost immediately afterwards he saw a tremendous flame shoot out of the closet window next door. He then ran into Messrs. Gerrard's and heard several loud explosions, and flames flew out to a distance of about 10ft. As there was nobody present who knew how to cut off the electric current witness went to Vine-street Police-station, where an inspector advised him to send to the Grosvenor Gallery. Witness despatched a messenger thither, but, in the interim, fearing the premises would catch fire, he gave the deceased a pair of shears and told him to get out of the first-floor window and cut the electric light wire. He said he could do it better on the roof, and before witness could speak he had got to the top of the house. The flame and explosions suddenly ceasing, witness concluded that the current had been turned off at the Gallery. A moment later he heard a crash, and eventually discovered that the deceased had fallen through a skylight from a height of 60ft. He was found in the cellar quite dead. In reply to Mr. Hayward witness said the flames he had spoken of were absolute fire, and not merely reflection. Everybody was very much excited.—Dr. J. R. Kemp, of 101, Regent-street, who made a post-mortem examination, said the cause of death was a fracture of the skull and concussion of the brain. He was quite satisfied that the unfortunate lad was not killed by the electric current. There were always peculiar symptoms in cases of death by electricity.—Mr. G. L. Addenbrooke, 9, Mecklenburgh-street, engineer in the service of Sir C. Lindsay and Co., said the business was known as the Grosvenor Gallery Electric Light Supply. It was formed for the supply of the electric light to general consumers. He had examined the house where the accident happened, and found at the point where the wires entered the premises that a spark had passed two or three times and slightly blistered the paint. Water had come through the roof of the closet in considerable quantities, and had saturated the wires at the point where they entered the fuse box, and the proximity of the water seemed to have allowed an intermittent passage of a slight current. If the current had attained great dimensions the fuse in the engine room would have given way, and the supply have been immediately cut off. In cutting through the gutta percha covering of the wire the deceased might or might not have received a shock of a slight character. The flame which Mr. Davis and the police-constable had described would be an electric spark 4in. long, and blinding in its nature. Any one looking at it would think it was a flame. The shears the deceased was using would act as a conductor, but as the current would be only the "leakage to earth," the shock would be very small indeed, and not sufficient to destroy life. The explosions which had been spoken of would be caused, he thought, by the spark igniting water which had been decomposed by the current. —John Rahter, an assistant in the employ of Messrs. Gerard and Co., said he was coming downstairs when he saw bright flames issuing from the closet in which the battery was kept. He attempted to turn off the supply, but failed, and Mr. Davis coming into the shop suggested to witness to cut the wires, or the shop would be burned down. Witness replied that it would be dangerous to cut the wires, but Mr. Davis took a pair of shears into his own shop and sent the lad to cut them. In answer to the jury, witness said that the flames issuing from the battery seemed like real fire. After further evidence the jury returned a verdict to the effect that the deceased was killed by a fall from the roof of the premises; there was not sufficient evidence to show whether he received an electric shock or not. They also wished to state that the electric light companies should supply their customers with printed rules warning them of the danger attached to meddling with the electric wires." We confess our inability to account satisfactorily for these "flames 10ft. long" and the series of loud explosions which Mr. Davis bore witness to. It is scarcely possible to admit Mr. Addenbrooke's suggestion as to the explosion being due to gas, resulting from the decomposition of water. Under practical conditions an alternating current is of course unable to decompose water. A much more feasible hypothesis is that the gas fittings were to blame and the explosions were due to coal gas, ignited by a spark at the place where the fault in the insulation was afterwards discovered.

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 187.)

Ruhmkorff's induction coil consists of a primary coil surrounding a soft iron core. The current in this coil is made intermittent by means of a spring carrying a small piece of iron, which is in front of one end of the core, and which is attracted by the magnetism of the core as soon as the current flows, and, moving in obedience to this attraction, breaks a contact between a small piece of platinum attached to the spring and a piece of platinum on the end of an adjustable screw, thus stopping the current, destroying the magnetism, and allowing the spring to return and again make contact. Sometimes separate clock-work breaks, or tuning forks, are used in place of the vibrator, to render the current intermittent. Around the primary coil is wound a great length of fine wire, constituting the secondary coil. The coefficient of mutual induction between the primary and secondary wires will be nearly proportional to the number of turns in the secondary coil, and may, therefore, be made very great. When contact is made in the primary circuit the current will begin to flow, and will steadily increase in the primary coil. The induced electromotive force in the secondary will be proportional to the rate of increase of the primary current. This will depend on the electromotive force of the battery, but will be retarded by the self-induction of the primary coil, with its iron core, and cannot, therefore, be made very great. Hence, the electromotive force of the secondary coil, when the primary current is started, can never be very great.

On breaking the primary circuit, however, the current can be stopped comparatively quickly by causing the contact breaker to move sufficiently rapidly, and thus to throw into the circuit a very great air resistance in a very small fraction of a second. Thus, the primary current can be stopped much more quickly than it was generated, and a correspondingly greater electromotive force may be generated in the secondary coil.

But, however quickly the vibrator may move, there must be an amount of work done by the current before it ceases equal to that done by the battery against the opposing electromotive force of self-induction in starting the current, and consequently the primary current will leap over any space of air rather than cease suddenly on breaking contact, and will continue for a certain interval before it is completely dead. Hence, a contrivance is adopted in the Ruhmkorff coil by which the primary current may expend its energy very rapidly. This consists in connecting a condenser of very great capacity with the terminals of the primary coil. On breaking contact in the primary circuit the electromotive force of self-induction, instead of sending a current across the gap where the contact is broken, sends a current into the condenser, charging it up to a high potential, and, as it meets with no sensible resistance, it expends its energy in charging the condenser in a very short time indeed, and then ceases. Thus the rate of diminution of the primary current is very great indeed, and the electromotive force in the secondary correspondingly increased. Moreover, as soon as the primary current ceases, the charged condenser produces a reversed current in the primary until it has discharged itself, thus prolonging the electromotive force in the secondary. By this contrivance the sparks at the contact breaker are very much diminished, while an electromotive force is obtained in the secondary coil capable of sending spark discharges through great lengths of air. This explains why long sparks can be obtained from an induction coil when the primary circuit is broken, but not when it is made.

The induction in a Ruhmkorff coil might be rendered more complete by connecting the ends of the iron core by means of iron bars passing longitudinally along the outside of the secondary coil, so that the lines of force of the primary coil may have a complete circuit in iron embracing both coils.

If the terminals of the secondary coil be connected with the coatings of a Leyden jar the sparks obtained will be brighter, on account of the accumulation of electricity, but not so long.

When an electric current is employed to produce motion in a conductor in a magnetic field, we have seen that an electromotive force is induced in the conductor, which opposes the current, and thereby causes its diminution. The work done by the current against this opposing electromotive force represents the useful mechanical work done in moving the conductor. The work so done in a unit of time is proportional to the opposing electromotive force and to the strength of the current. Thus the work done by the agent which transmits the current consists of two parts, one of which is employed in doing useful work in driving the "motor," while the other part is wasted in the production of heat caused by the passage of the current. If E denote the electromotive force urging the current, e the opposing electromotive force induced by the motor, and C the current, the whole work done in sending the current will be E C; and of this e C will represent the useful work done on the motor, while (E − e) C will represent the energy wasted in the circuit on account of electrical resistance. For, the resultant electromotive force in the circuit, from which the current is determined by Ohm's law, is E − e, and the work done against electrical resistance by this E.M.F. in sending a current C, which is equal to $\frac{E-e}{R}$, must be (E − e) C.

The efficiency of the system is represented by the ratio of the mechanical work done on the motor to the whole work expended in producing the current, and this is equal to the ratio of e C to E C, or $\frac{e}{E}$. In order to gain the greatest efficiency e should be made as large as possible in comparison with E. The rate at which work is done upon the motor (measured in *watts*) is e C, the electromotive force being expressed in volts and the currents in amperes. Expressed in horse-power it is $\frac{eC}{746}$ nearly. If R denote the resistance of the whole circuit, C is equal to $\frac{E-e}{R}$. Hence the rate of doing work upon the motor is represented by $\frac{e(E-e)}{R}$. If e be nearly equal to E this expression becomes very small, so that the horse-power of the motor becomes very small, unless R, the resistance of the whole circuit, is correspondingly reduced. Hence, when the resistance of the circuit is given, a great rate of doing work, or horse-power, is inconsistent with a high rate of efficiency. The greatest horse-power in the motor is obtained by making e equal to $\frac{1}{2}$ E when E is given. In this case one half of the work done in driving the current appears as mechanical work done upon the motor, and the other half is wasted as heat produced by the electrical resistance of the circuit, so that the efficiency of the system is one-half. If we consider only the electrical conditions and neglect mechanical resistance altogether the greatest efficiency will be obtained by making e sensibly equal to E. This may be done by sufficiently increasing the speed of the motor. For this purpose the couple which resists the rotation of the armature of the motor must be very small, and notwithstanding the high speed of the motor the work done by it in a second will be very small on account of the smallness of the current, unless the resistance of the circuit be extremely small. Of course if we take into account the mechanical resistance of the motor (arising from friction, &c.), we find that at high speeds a very large percentage of the work done in driving the motor is wasted by its own internal friction, &c., and this assigns a speed for maximum efficiency much less than that which would reduce the current to zero. In order to obtain a high rate of efficiency with great horse-power we must make the electrical resistance of the circuit as small as possible. We should always employ as large an electromotive force, E, as can be secured with the low resistance of the circuit, and drive the motor at high speed so as to make the ratio of e to E considerable.

In the above investigation we have supposed our motor theoretically perfect, for no theory will allow us to neglect the electrical resistance of the circuit. In many motors, as in most dynamos, the revolving armature is furnished with an iron core. In this core induced currents are set up which oppose the motion of the armature, and the work done against this

Digitized by Google

resistance appears as heat in the armature itself. The iron is used in order to concentrate the magnetic field upon the armature and thus increase the horse-power of the arrangement, but the work done against the currents induced in the iron is absolutely wasted, and thus diminishes the efficiency of the system. There may also be a considerable amount of work done in changing the magnetism of the iron as the armature revolves, and this also will be wasted and detract from the efficiency of the system. The evil effect of the currents induced in the iron is reduced to a minimum in the Gramme machine by employing iron wire instead of continuous metal in the armature, so that the induced currents tend to pass through the iron at right angles to the axis of the wire and thus meet with great resistance in passing from strand to strand. In consequence of this the induced currents are always very small, but the magnetic lines of force pass through the armature along the wires and thus meet with little resistance, or, in other words, find a path of great magnetic permeability. In the Edison armature the iron is in the form of thin discs, which are separated from each other by sheets of paper which prevent induced currents while the magnetic lines of force pass across the armature in the planes of the disc. In some motors and dynamos iron is altogether dispensed with in the armatures, and the magnetic field is sufficiently concentrated upon the wire of the armature by special arrangements of the field-magnets. When much power is lost by induced currents in the armature the evil is indicated by a corresponding rise of temperature. Most of the machines referred to above are generally used for the production of currents rather than as motors, but all dynamos or magneto electric machines which produce a continuous current in one direction are reversible, and can be used as motors, and the same remarks apply to the action of the iron in either case. In the large Edison dynamos a blast of air is driven by a fan around the armature to prevent a rise of temperature which would be injurious to the insulating material.

(To be continued.)

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XXXV.

BY OLIVER HEAVISIDE.

(Continued from page 145.)

The Transfer of Energy and its Application to Wires. Energy Current.

When the sage sits down to write an elementary work he naturally devotes Chapter I. to his views concerning the very foundation of things, as they present themselves to his matured intellect. It may be questioned whether this is to the advantage of the learner, who may be well advised to "skip the Latin," as the old dame used to say to her pupils when they came to a polysyllable, and begin at Chapter II. If this be done, Prof. Tait's "Properties of Matter" is such an excellent scientific work as might be expected from its author. But Chapter I. is metaphysics. There are only two Things going, Matter and Energy. Nothing else is a thing at all; all the rest are Moonshine, considered as Things.

However this be, the transfer of energy is a fact well known to all, even when we put the statement in such a form that the energy seems to lose its thinginess, by calling it the transfer of the power of doing work. Thus, after transfer of energy from the sun ages ago, followed by long storage underground and convection to the stove or furnace, we set free the imprisoned energy, to be generally diffused by the most varied paths. The transfer from place to place can be, in the great measure, traced so far as quantity and time are concerned; but it does not seem possible to definitely follow the motion of an atom of energy, so to speak, or to give a fixed individuality to any definite quantity of energy.

Whenever the dynamical connections are known, the transfer of energy can be found, subject to a certain reservation. In the elementary case of a force, F, acting on a particle of mass m and velocity v, F is measured by the rate of acceleration of momentum, or $F = m\dot{v}$; and, to obtain the equation of activity, we merely multiply this equation by the velocity, getting $Fv = mv\dot{v} = \dot{T}$, the rate of increase of the kinetic energy T, or $\frac{1}{2}mv^2$, which is the amount of work the particle can do against resistance in coming to rest. Where the energy came from is here left unspecified. In a case of impact we may clearly understand that the transfer of kinetic energy is from one of the colliding bodies to the other through the forces of elasticity brought into play, thus making potential energy an intermediary, though what the potential energy may be, and whether it is not itself kinetic, or partly kinetic, we are not able to decide.

It is much more difficult in the case of gravity. As the stone falls to the ground, it acquires kinetic energy truly; and if energy moves continuously, as its indestructibility seems to imply, it must receive its energy from the surrounding medium; or the energy of gravitation must be in space generally, wholly or in part, and be transferred through space by definite paths through stresses in the medium, by which means Maxwell endeavoured to account for gravitation. In general, we have only to frame the equations of motion of a continuous system of forces, and it stands to reason that the transfer of energy is to be got by forming the equation of activity, not of the system as a whole, but of a unit volume.

Now, in the admirable electromagnetic scheme framed by Maxwell, continuous action through space is involved, and the kinetic and potential energies (or magnetic and electric) are definitely located, as well as the seat and amount of dissipation of energy. We therefore need only form the equation of activity to find the transfer of energy vector. Of course impressed forces are subject to the energy definition. No other is possible in a dynamical system.

But if we take Maxwell's equations and endeavour to immediately form the equation of activity (like $Fv = \dot{T}$ from $F = m\dot{v}$), it will be found to be impossible. They will not work in the manner proposed. But we may consider the energy, electric and magnetic, entering and leaving a given space and that dissipated within it, and by laborious transformations evolve the expression for the vector transfer. This was first done by Prof. Poynting for a homogeneous isotropic medium (*Phil. Trans.*, 1884). In my independent investigation of this matter, I also followed this method in the first place (*The Electrician*, June 21, 1884) in the case of conductors. But the roundabout nature of the process to obtain what ought to follow immediately from the equations of motion, led me to remodel Maxwell's equations in some important particulars, as in the commencing sections of this article (Jan., 1885) with the result of producing important simplifications, and bringing to immediate view useful analogies which are in Maxwell's equations hidden from sight by the intervention of his vector potential. This done, the equation of activity is at once derivable from the two cross connections of electric force and magnetic current, magnetic force and electric current, in a manner analogous to $Fv = \dot{T}$, without roundabout work, and applicable without change to heterogeneous and heterotropic media, with distinct exhibition of what are to be regarded as impressed forces, electric and magnetic. (*Electrician*, Feb. 21, 1885).

Knowing the electric field and the magnetic field everywhere, the transfer of energy becomes known. The vector transfer at any place is perpendicular to both the electric and the magnetic forces there, not counting impressed forces. Its amount per unit area equals the product of the intensities of the two forces and the sine of their included angle.

But I mentioned that there is a reservation to be made. It is like this. If a person is in a room at one moment, and the door is open, and we find that he is gone the next moment, the irresistible conclusion is that he has left the room by the door. But he might have got under the table. If you look there you can make sure. But if you are prevented from looking there, then there is clearly a doubt whether the person left the room by the door or got under the table hurriedly. There is a similar doubt in the electromagnetic case in question, and in other cases. Thus, we can unhesitatingly conclude from the

Digitized by Google

properties of the magnetic field of magnets that the mechanical force on a complete closed circuit supporting a current is the sum of the electromagnetic forces per unit volume (vector product of current and induction), but it does not follow strictly that the so-called electromagnetic force is the force really acting per unit volume, for any system of forces might be superadded which cancel when summed up round a closed circuit.

So, in the transfer of energy case, there may be any amount of circulation of energy in closed paths going on (as pointed out in another manner by Prof. J. J. Thomson), besides the obviously suggested transfer, provided this superposed closed circulation is without dissipation of energy. Or, if W be the vector energy current density, according to the above-mentioned rule, we may add to it another vector, say *w*, provided *w* have no convergence anywhere. The existence of *w* is possible, but there does not appear to be any present means of finding whether it is real, and how it is to be expressed.

Its consideration may seem quite useless, in fact. But it is forced upon us in quite another way, by the fact that when $w=0$ we are sometimes led to the closed circulation of energy. Let, for instance, a magnet be placed in the field of an electrified body; or, more simply, let a magnet be itself electrified. There is no waste of energy; hence the flow of energy caused by the coexistence of the two fields, electric and magnetic, is entirely in closed paths, which, in the case of a spherical uniformly magnetised body, uniformly superficially electrified, are circles in parallel planes perpendicular to the axis of magnetisation, the circles being centred on this axis. This closed circulation is entirely through the air or other dielectric. What is the use of it? On the other hand, what harm does it do? And if the medium is really strained by coexistent electric and magnetic stresses, why should there not be this closed circulation? But, if we like, we may cancel it by introducing the auxiliary *w*.

There is yet another kind of closed circulation, according to W alone, not existing by itself, but set going by impressed forces causing a useful transfer of energy, and ceasing when the useful transfer ceases. If, for instance, we close a conductive circuit containing a battery, we set up a useful transfer from the battery to all parts of the wire, through the dielectric usually. Suppose there is also impressed electric force in the dielectric, or electrification, or any stationary electric field. If the battery does not work there is no transfer of energy. But when it does, there is, besides the regular first mentioned transfer from the battery to the wire, a closed circulation due to the coexistence of the stationary electric field and the magnetic field of the wire current, the resultant transfer being got by superposing the regular and the closed circulations. Here again, by introducing *w*, we may reduce it to the regular undisturbed transfer. It is clear, then, in considering the nature of the transfer in a useful problem, that it is of advantage to entirely ignore the useless transfer, and confine our attention to the undisturbed.

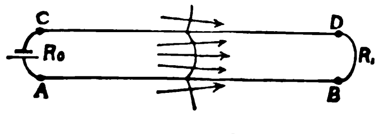
A general description of the transfer along a straight wire was given in Section II. (January 10, 1885). It takes place, in the vicinity of the wire, very nearly parallel to it, with a slight slope towards the wire, as there described. Prof. Poynting, on the other hand (Royal Society, *Transactions*, February 12, 1885), holds a different view, representing the transfer as nearly perpendicular to a wire, *i.e.*, with a slight departure from the vertical. This difference of a quadrant can, I think, only arise from what seems to be a misconception on his part as to the nature of the electric field in the vicinity of a wire supporting electric current.

The lines of electric force are nearly perpendicular to the wire. The departure from perpendicularity is usually so small that I have sometimes spoken of them as being perpendicular to it, as they practically are, before I recognised the great physical importance of the slight departure. It causes the convergence of energy into the wire. To estimate the amount of departure, we may compare the normal and tangential components of electric force. Let there be a steady current in a straight wire, and the fall of potential from beginning to end be $V_0 - V_1$; the tangential component is then $(V_0 - V_1) \div l$, if l be the length of wire. On the other hand, the fall of potential from the wire to its return, of no resistance, for simplicity, at any distance from the beginning of the line, is V, which is V_0 at one end and V_1 at the other. It is clear at once that the tangential is an exceedingly small fraction of the normal component of electric force, if the wire be long, and that it is only under quite exceptional circumstances anything but a small fraction. Prof. Poynting should therefore make his tubes of displacement stick nearly straight up as they travel along the wire, instead of having them nearly horizontal, unless I have greatly misunderstood him.

But if we distribute the impressed force uniformly throughout the circuit, so that there shall be, in the steady state, no difference of potential and no transfer of energy, owing to the impressed force at any place being just sufficient to support the current there—then, on starting the impressed force, the transfer of energy will be perpendicular to the wire outward, ceasing when the steady state is reached; and, on the other hand, on stopping the impressed force the transfer will be perpendicular to the wire inward, the magnetic energy travelling back again (assisted by temporary longitudinal electric force, which has no existence in the steady state) to be dissipated in the wire. But this case, though imaginable, is not practically realisable.

In the vicinity of the wire the radial electric force varies inversely as the distance, and so does the intensity of magnetic force. The density of the energy current therefore varies inversely as the square of the distance approximately. This does not continue indefinitely. Thus, if the return be a parallel wire the middle distance is the place of minimum density of the energy current, in the plane of the two wires. As regards the total energy current, this is VC, the product of the fall of potential from one wire to the other into the current in each. One factor, V, is the line integral of the electric force across the dielectric. The other, C, is the line integral $(\div 4\pi)$ of the magnetic force round either wire.

In the figure *ab* and *cd* are the two wires, enormously shortened in length compared with their distance apart, joined



through terminal resistances R_0 and R_1, in the former of which alone is the impressed force *e*. The fall of potential from *a* to *c* is V_0, from *b* to *d* is V_1, and at any intermediate distance is V. The total activity of the source is eC, of which $(e - V_0)$ C is wasted in R_0. What is left, or V_0C, is the energy current at *ac*, entering the line. By regular waste into the wires, its strength falls to V_0C at *bd*, where the line is left, and the terminal arrangement entered, to be wasted in frictional heat generation R_1C^2 therein, or otherwise disposed of. The curved lines and arrows perpendicular to them show lines of electric force and the direction of the energy flow at a certain place, the inclination of the lines of force to the perpendicular being greatly exaggerated, as well as that of the lines of flow of energy to the horizontal, in order to show the convergence of energy upon the wires, there to be wasted. Its further transfer belongs to another science.

The rate of decrease of VC as we travel along the line is the waste per unit length. Thus,

$$-\frac{d}{dx}(\mathrm{VC}) = -\mathrm{C}\frac{d\mathrm{V}}{dx} = (\mathrm{R}_1 + \mathrm{R}_2)\mathrm{C}^2 \quad . \quad . \quad (81b)$$

R_1 and R_2 being the resistances of the wires per unit length. This is in steady flow, with no leakage. But if there be leakage, we have the equation of continuity

$$-(d\mathrm{C}/dx) = \mathrm{KV},$$

making

$$-\frac{d}{dx}(\mathrm{VC}) = \mathrm{KV}^2 + (\mathrm{R}_1 + \mathrm{R}_2)\mathrm{C}^2 \quad . \quad . \quad . \quad (82b)$$

where KV^2 is the waste heat per second due to the leakage resistance.

But when the state is not steady, we have the equation of continuity

$$-\frac{d\mathrm{C}}{dx} = \mathrm{KV} + \mathrm{S}\dot{\mathrm{V}} \quad . \quad . \quad . \quad (80b)\ bis.$$

and the equation of electric force

$$-\frac{d\mathrm{V}}{dx} = \mathrm{L}_0\mathrm{C} + \mathrm{E} - \mathrm{F} \quad . \quad . \quad (73b)\ bis.$$

Digitized by Google

so that

$$-\frac{d}{dx}(\mathrm{VC}) = \mathrm{KV}^2 + \frac{d}{dt}(\tfrac{1}{2}\mathrm{SV}^2) + \frac{d}{dt}(\tfrac{1}{2}\mathrm{L}_0\mathrm{C}^2) + \mathrm{EC} - \mathrm{FC} \qquad (83)$$

Here we account for the leakage heat, for the increase of electric energy, and for the increase of magnetic energy in the dielectric by the first, second, and third terms on the right side. EC, the fourth term, represents the energy entering the first wire per second, E being the tangential electric force; and – FC, the last term, represents the energy entering the second wire per second, F being the tangential electric force at its boundary reckoned the same way as E. The energy flow is now perpendicular to the current, *i.e.*, after entering the wires, ceasing when the axes are reached. And,

$$\mathrm{EC} = \mathrm{Q}_1 + \dot{\mathrm{T}}_1, \qquad -\mathrm{FC} = \mathrm{Q}_2 + \dot{\mathrm{T}}_2 \quad . \quad . \quad (84b)$$

if Q_1, Q_2 are the dissipativities, T_1 and T_2 the magnetic energies in the two wires, per unit length of line.

If the impressed force is a S.H. function of the time, so is the current, &c., everywhere, and

$$\mathrm{E} = \mathrm{R}'_1\mathrm{C} + \mathrm{L}'_1\dot{\mathrm{C}}, \qquad -\mathrm{F} = \mathrm{R}'_2\mathrm{C} + \mathrm{L}'_2\dot{\mathrm{C}} \quad . \quad (85b)$$

where R_1', R_2', L_1', and L_2' are constants depending upon the frequency, reducing to the steady-flow resistances and inductances when the frequency is infinitely low. In this S.H. case

$$\mathrm{Q}_1 = \tfrac{1}{2}\mathrm{R}'_1\mathrm{C}_0^2, \quad \mathrm{Q}_2 = \tfrac{1}{2}\mathrm{R}'_2\mathrm{C}_0^2, \quad \mathrm{T}_1 = \tfrac{1}{4}\mathrm{L}'_1\mathrm{C}_0^2, \quad \mathrm{T}_2 = \tfrac{1}{4}\mathrm{L}'_2\mathrm{C}_0^2,$$

are the *mean* dissipativities and magnetic energies in the wires, C_0 being the amplitude of the current; the halving arising from the mean value of the square of a sinusoidal function being half the square of its amplitude. But in no other case is there anything of the nature of a definite resistance, although, if the magnetic retardation to inward transmission is small, we may ignore it altogether, and drop the accents in (85*b*).

(To be continued.)

CORRESPONDENCE.

SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the last issue of your journal I find notice given of a storage cell brought out by the "Union Electrical Power and Storage Company," which apparently consists, as to the negative plates, of an agglomerated mass of peroxide of lead fixed in frames or edgings of celluloid, and, as to the positives, of spongy metallic lead similarly framed, but with the addition of strips of lead; electrical contact being made by a strip of platinum.

May I ask you to publish for general information the following epitomised extracts from one of my early patents, No. 5,631 of 1881, being the third taken out by me in that year, in which I describe plates, supports, retainers, or frames of any suitable form for the retention of active material (upon, or in which the active material may be fixed or placed in a finely divided pasty, deposited or compound condition), constructed of materials not readily subjected to the destructive influence of oxidation or other destructive action, and specifying, amongst other materials, "cellulose, either alone or in combination with platinum, such combination forming a terminal." My claim reads as follows:—"The construction of terminal plates, supports, retainers, or frames employed in secondary batteries, of a material not readily subjected to the destructive influence of oxidation in the manner and for the purpose herein described."—Yours, &c., JOHN S. SELLON.

January 12th, 1887.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My company have been informed that the Electrical Power Storage Company have to-day written a letter to the Union Electrical Power and Light Company stating that the batteries referred to in a printed description issued by the latter company are an infringement of certain patents held by the Electrical Power Storage Company.

As my company have sold the Letters Patent under which these batteries are made to the Union Company, I am instructed to say that such batteries are not an infringement of any Letters Patent owned by the Electrical Power Storage Company, and, furthermore, that within the last month Counsels' opinions have been taken and careful investigation of specifications have been made at the patent office, both of which clearly show that the Electrical Power Storage Company's patents are not novel, have been anticipated, and are consequently invalid so far as they have anything in common with the patents sold to the Union Company.

The Union Company are, I understand, prepared to defend any proceedings that the Electrical Power Storage Company may see fit to take, and so are we. The Electrical Power Storage Company must be aware from past experience that the position they take up is untenable.—Yours, &c.,

By order, D. ARMYTAGE DAVIS, Secretary.

Primary Battery Company, Limited, 11, Queen Victoria-street, London, E.C., January 13th, 1887.

WALKER'S SULPHUR SAL-AMMONIAC BATTERY.

We are informed by Mr. Sydney Walker that he has invented a battery which he describes in the following terms: "This battery is exactly similar to the Leclanché, except that in place of the oxide of manganese used as a depolariser, pure sulphur of the size of a pea or small bean is used; and that the proportion of sulphur required is smaller, both by weight and by volume than that of the oxide of manganese generally employed. Its E.M.F. is a trifle below that of the porous cell Leclanché, while its resistance is very much less. The internal resistance and life of the cell can be varied within large limits by altering the proportions of sulphur and carbon employed. More sulphur gives a longer life for given work and higher resistance, more carbon gives lower resistance and shorter life. The ordinary life is about the same as Leclanché. The cell also possesses the valuable property of giving warning when it is worked out, or if subjected to an undue strain. In the working of the battery sulphuretted hydrogen is formed; but does not come away unless the battery is worked very hard, or is nearly worked out, so that warning is given in the case of leakage, on house bell wires say, that will be very valuable. The amount of the gas given off is never sufficient to be noxious, even under the conditions named.

The action of the cell appears to be as follows:—

Starting with	$2Zn$,		$2NH_4Cl$,	S,	C.
First	Zn,	$ZnCl_2$,	$2NH_3$,	H_2S,	C.
Next	Zn,	ZnS,	2HCl,	$2NH_3$,	C.
Next	Zn,	ZnS,	$2NH_4$	Cl,	C.

so that the whole of the work of the cell is done at the expense of the sulphur."

[Mr. Walker, of course, does not mean to overlook the expenditure of zinc —ED. *E.*]

MAGNETIC ORE SEPARATOR.—This apparatus, designed by J. Wenström, of Stockholm, for the concentration of magnetic iron ore, consists of a stationary electro-magnet supported by two spindle axes in a wooden stand. The magnet consists of an excentric iron cylinder provided with flanges, between which the conducting wire is wound in such a way that the current forms the north and south poles at the outer edges of the flanges, the adjacent flanges having different polarity. The current is conducted from a dynamo into the apparatus by means of insulated wires through one of the spindles. Around the magnet a drum rotates on the spindles. The drum consists of a number of parallel soft iron rods separated from each other by wood. The ore enters at the top of the drum, and follows its rotation; the non-magnetic portions falling after a quarter revolution, and the magnetic ore being firmly held by the magnetic iron rods. After another quarter revolution this falls into the ore hutch. Ore intimately associated with gangue must be first comminuted and washed. The ore obtained in a recent trial was, in volume, somewhat more than half of the material treated. The deads were not weighed.—*Journal* Inst. Civ. Eng.

1886.

Continuing our description of some of the latest types of the Crompton dynamos, we come to the machine illustrated in Fig. 11, which is designed for electro-plating work in series. This machine has an output of 54 units, equal to 72·5 electrical horse-power. At 700 revolutions it yields 110 volts at the terminals, and 490 amperes, requiring 80·25 horse-power on the driving pulley. The commercial efficiency is thus 90·3 per cent., the electrical efficiency is 94·5 per cent., and the total efficiency of conversion is 97 per cent. The machine weighs $2\frac{1}{2}$ tons, and contains 1,030lbs. of copper. This gives 10·4 watts per lb. of total weight, and 52 watts per lb. of copper. The measurement is 6ft. 2in. by 5ft. 10in. by 2ft. 6in. The field is compound-wound for constant potential, the magnets, four in number, being forged of the best scrap iron, and weighing 1 ton 15cwt. The total ampere turns on the field coils amount to 11,600, of which 9,200 are supplied by the shunt coils. The current in the shunt coils equals 11·5 amperes, and in the series coils 123 amperes *each*. The resistance of the shunt coils as connected is 8·8 ohms, and that of the series coils is ·005 ohm. The armature is of the Gramme ring type, and has the following dimensions:—Axial length, 15·5in.; diameter, 15·5in.; radial depth, 3·125in. It contains 111 yards of bar or strip copper of an *average* sectional area equal to ·15 square inch, and a resistance between the brushes of ·004 ohm. The current density is 1,600 amperes per square inch, and 1,280 watts are lost in the armature with full load. The armature has only one turn for each of the 96 sections of the commutator. The weight of iron in the armature is about 5cwt., and of copper 206lb. This gives 262 watts per lb. of armature copper, and 1 volt per yard of conductor. The armature field is equal to 18 lines per square inch. The peripheral velocity is 2,840ft. per minute, and the bearings are 10in. in length, of cast iron, with white metal run in.

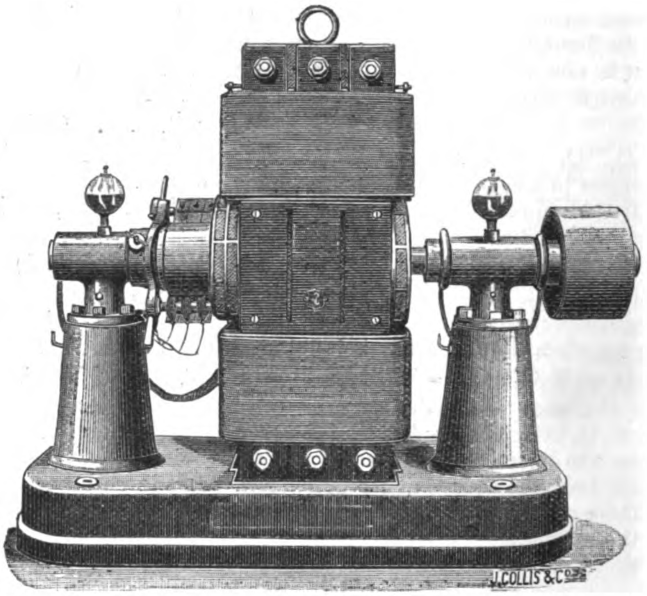

FIG. 11.—The Crompton Plating Dynamo.

In the armature of this machine Mr. Crompton has introduced an improvement, with a view to reducing the loss due to Foucault currents in the bars. The plan adopted is illustrated in Fig. 12.* It will be seen that the method adopted consists in splitting each bar in half longitudinally and crossing one half under the other at the central section. This does not, of course, entirely obviate the production of Foucault currents, but by halving these currents in each section of the bar the watts lost are, of course, reduced to one fourth for each half. The sections in Fig. 12 will readily be understood without further explanation.

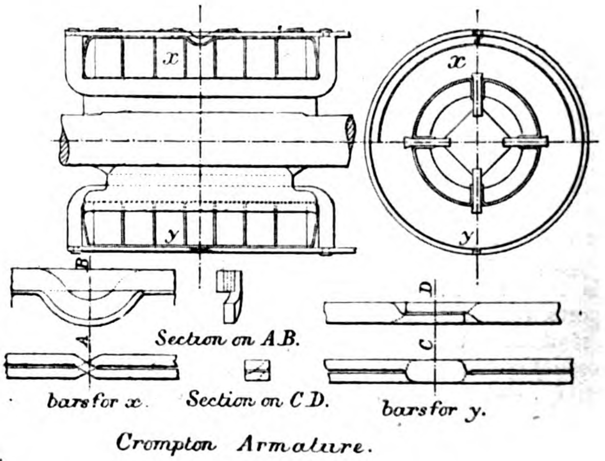

FIG. 12.

We have not yet exhausted the whole of the information with which this firm has kindly supplied us, but we propose at this point to give, for the sake of comparison, an example of recent practice by one of the largest firms of dynamo builders upon the Continent.

* This figure was inserted in error in our last week's issue.

Messrs. PATERSON and COOPER construct the machines of the different types illustrated herewith. It will not be necessary to enter at length into the construction of these Phœnix machines, as they have been frequently described. Fig. 13

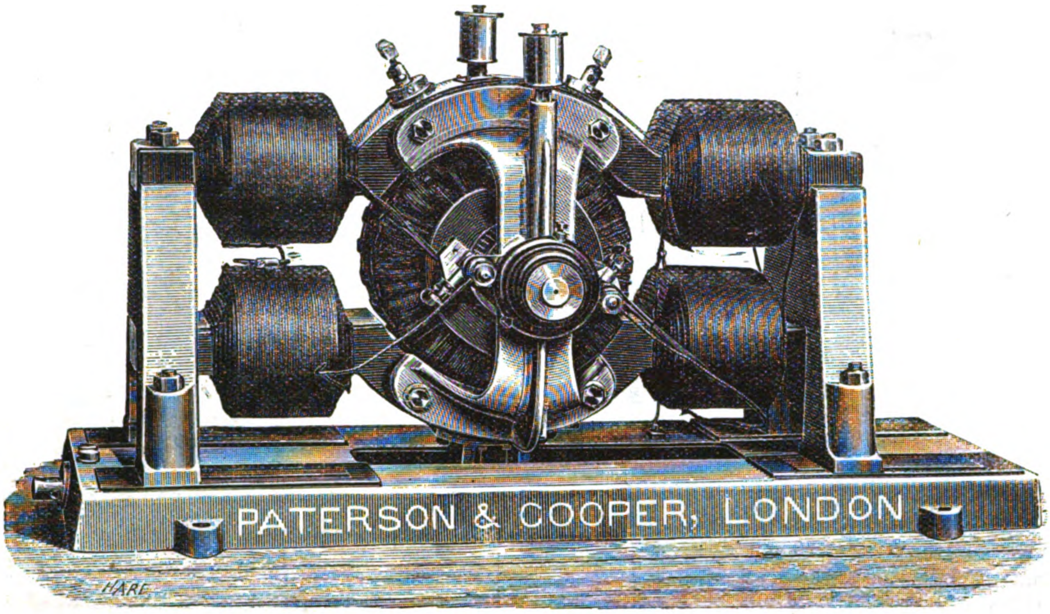

FIG. 13.—Phœnix Arc Light Dynamo.

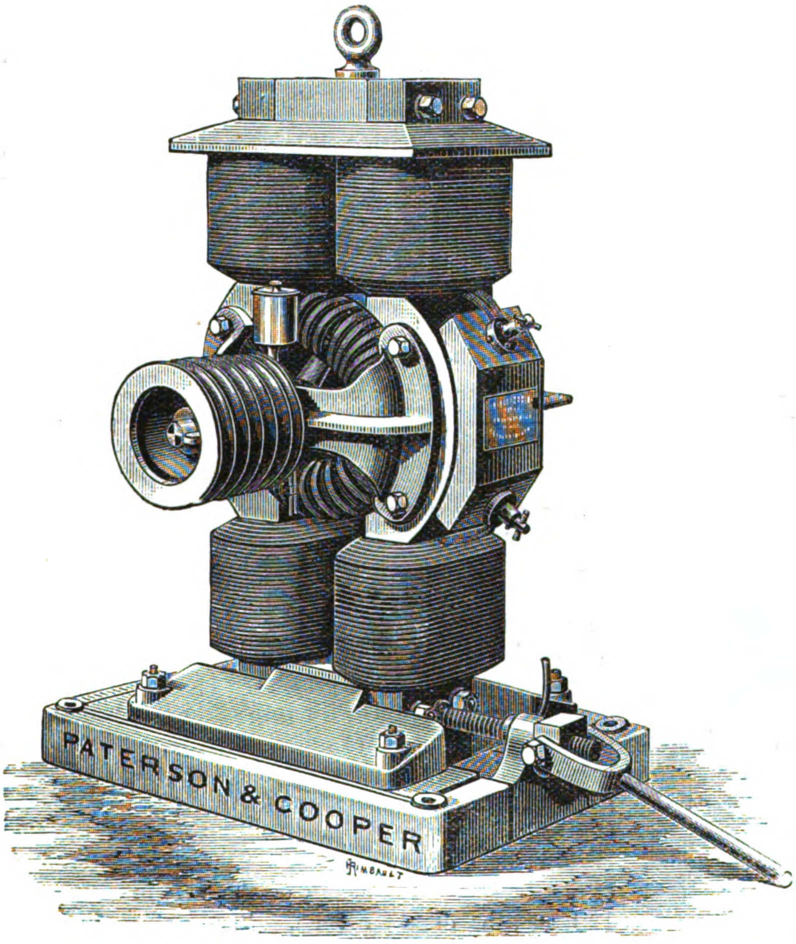

FIG. 14.—Vertical Phœnix Dynamo, driven by Belts.

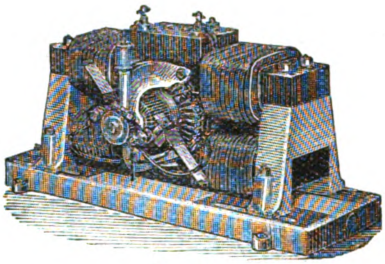

FIG. 15.
Horizontal Phœnix Dynamo, supplying 125 60-watt Lamps

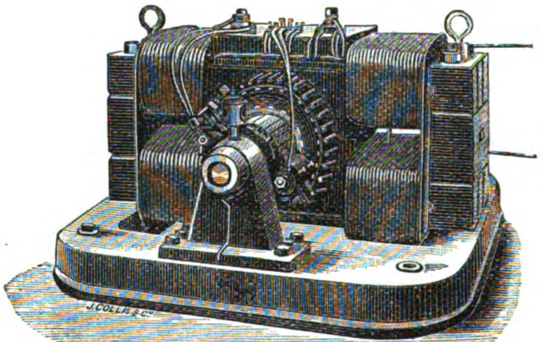

FIG. 16.
Horizontal Phœnix Dynamo, supplying 600 60-watt Lamps.

shows a dynamo constructed for fourteen arc lamps in series, each lamp requiring 50 volts and a current of from 8 to 10 amperes. It is intended to run at 1,000 revolutions per minute. Similar machines to this are in use for lighting the Covent Garden Theatre. The type is followed with machines up to 1,000 volts. Fig. 14 shows a vertical Phœnix dynamo of the pattern designed for ship lighting to be driven by belts or ropes. The dynamo, as will be seen, is mounted on a cast-iron bed plate, and is fitted with a screw-tightening gear. The speed is 1,000 revolutions, giving an E.M.F. of 110 volts and a current of 150 amperes, intended to supply 250 60-watt lamps. Fig. 15 shows a horizontal machine in-

tended to run at 1,150 revolutions, and to give 75 amperes at 110 volts, supplying 125 60-watt lamps. Machines of this type are made to supply from 100 to 300 lamps. Fig. 16 is also a horizontal type machine,

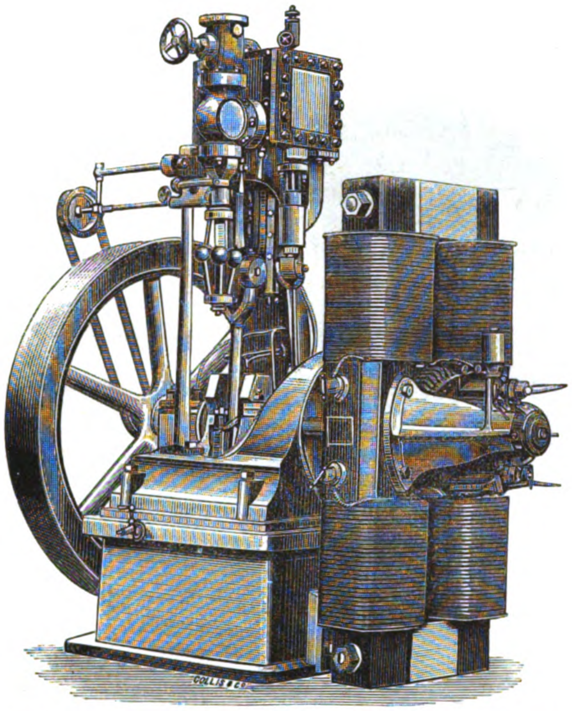

Fig. 17.—Ship Lighting Phœnix Dynamo, Driven Direct.

to give, at 650 revolutions, 360 amperes at 110 volts, and is intended to supply current to 600 60-watt lamps. Fig. 17

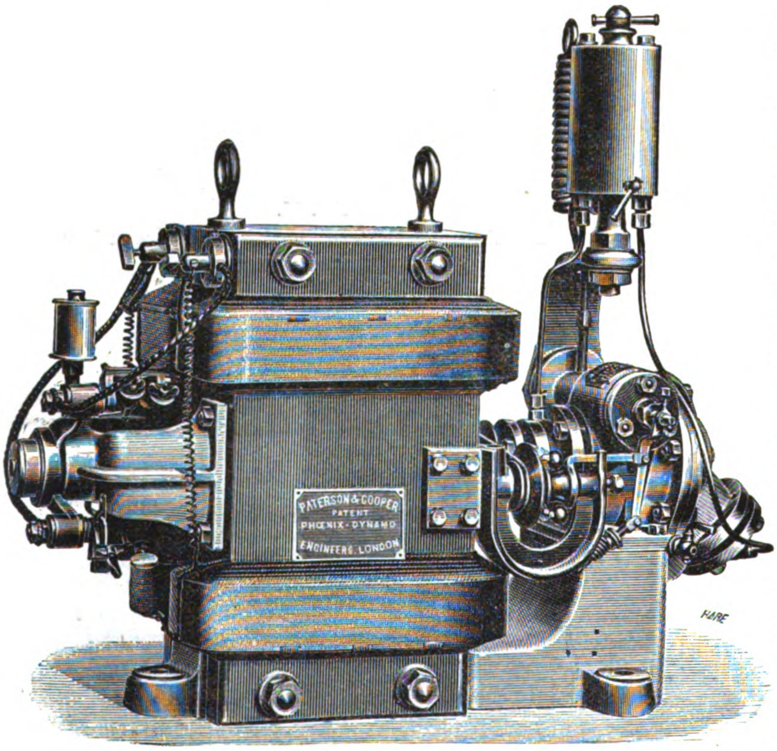

Fig. 18.—Phœnix Machine for Torpedo Boats.

illustrates a ship lighting direct-driven machine, coupled to a Gwynne engine, with a speed of 400 revolutions, supplying 100 60-watt lamps, with a current of 60 amperes, at an E.M.F. of 110 volts. Fig. 18 is a machine designed for torpedo boat lighting, coupled direct to a tower engine. It is made in two sizes, No. 1 size running at 750 revolutions, giving 50 amperes at 80 volts. The last machine made by this firm (shown in Fig. 19 below), is a small machine designed for arc lighting, and is intended to give current for one or two arc lamps requiring 8 to 10 amperes of current at 100 volts. The speed is 1,600 revolutions per minute. A similar class of machine is made for incandescent lighting.

Messrs. Ganz and Co., of Budapest, construct a direct current four-pole dynamo, possessing several features of interest. The machine is compound-wound, and may be termed

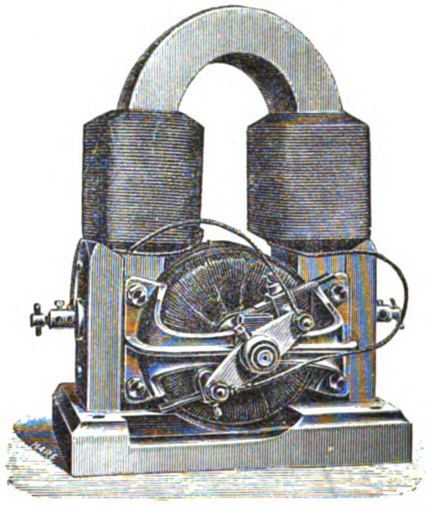

Fig. 19.—Paterson and Cooper's Small Dynamo, for Arc or Incandescent Lighting.

a 50-unit machine, the output being given as 50,400 watts, with an E.M.F. of 105 volts at the terminals, at 670 revolutions per minute. The horse-power required at the normal speed for the above output is given at 75·5, and the commercial efficiency 91 per cent., the electrical efficiency being 95·8 per cent. The compounding is intended to provide a constant potential at the end of a main in which 5 per cent. is lost when the full load is reached. The size of this machine over all is 1,440mm. by 1,285mm. by 780mm., and its weight 2,500kgs., *i.e.*, about $2\frac{1}{2}$ tons. The weight of iron magnetised is 1,500 kgs., or about 3,150lb.; that of copper is 240 kgs., or about 520lb. These figures give 20 watts per kilogramme of machine, or, say, 10 watts per lb. of whole weight, and 210 watts per kilogramme of total copper, say 100 watts per lb. of copper. The cores of the field-magnets are of wrought iron, the bedplates and pole-pieces of cast iron, the weight of the magnet cores being 560kgs., and the sectional area of the pole-pieces 920 sq. cm. The following details are given us with respect to the winding of the series and the shunt coils:—Firstly, as to the series coils: 4 coils are placed near the pole-pieces of the lateral magnets. In every coil four wires are wound parallel. One end of every coil is connected to one of the four brush holders, and two and two of them to the terminals of the machine. The length of the wire in each coil is 12·15cm., the diameter 6mm. Sectional area of wires through which whole main current passes 226 sq. mm., and the resistance 0·00215 ohm measured after machine had been running at full load for several hours. Amperes per coil 240, turns in each coil 15, turns for each magnetic circuit 15, ampere turns for each magnetic circuit 360, total ampere turns in series coils 14,400. Loss 495 watts, and current density 2·13 per sq. mm. Secondly, coming to the shunt coils,

Digitized by Google

we have two coils on the middle magnets, with 10 layers of 70 turns; four coils on the lateral magnets, with 10 layers of 68 turns. The whole six coils are connected in series and to the terminals of the machine. The length of wire on the middle magnets together is 1,540m., on the lateral magnets together 2,200m. The diameter of all wire is 2·4mm., and the sectional area is 4·5 square mm., resistance, as connected, 16 ohms after several hours run. Amperes 6·56, turns on middle magnets together 1,400, on lateral 2,720, ampere-turns on each middle magnet 4,590, and on lateral 4,450. Ampere-turns for each magnetic circuit 9,040. Total turns on the six magnets 4,120. Total ampere-turns on the six magnets 26,980. Watts lost 695. Current density 1·46 amperes per square mm. Taking the total coils, the ampere-turns for each magnetic circuit are 9,500, the total ampere-turns 41,380, and the watts lost 1,185

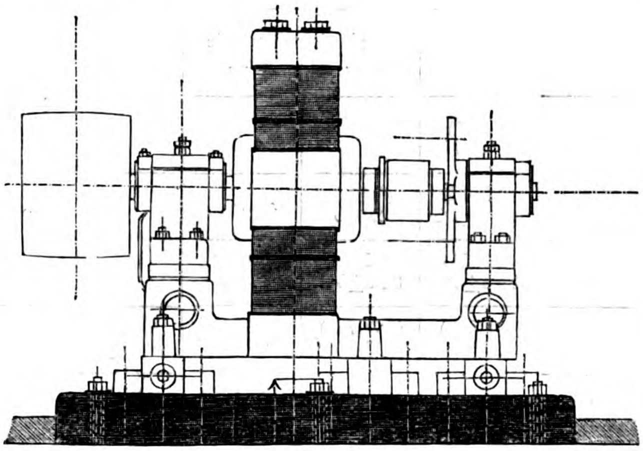

Fig. 20.

The armature is of the toothed drum type, built up of varnished sheets, with an axial length of 300mm., and a diameter of 420mm. The diameter of the field space is 433mm., the air space between teeth of armature and pole-pieces being

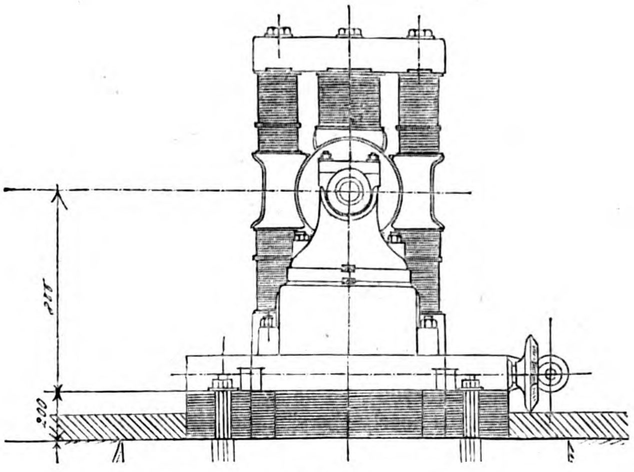

Fig. 21.

6 5mm. Number of teeth and channels 48, breadth of channel 13mm., depth 28mm.; number of wires in each channel 8, of diameter 5mm.; number of circuits between brushes 2. The total length of wire composing twenty-four turns is 29m., and total weight of wire used in winding in the armature 41kgs., including connections 50kgs. Sectional area of wire, 19·6 square mm. Watts lost in armature and connections to commutator, 995. Weight of iron in armature without axle, 190kgs. Watts per kg. of copper 1,008, *i.e.*, about 450 watts per lb. of wire. Volts per metre of wire, 3·73. Strength of magnetic field in armature, 17,900 C.-G.-S. units, or 19·5 lines of force calculated according to Kapp's formula. Strength of magnetic field on the boundary of the pole-pieces 5,480 C.-G.-S. units. The mechanical details show that the lengths of bearings are respectively 276 and 240mm.; diameter, pulley 550mm., breadth 400mm.; number of brushes, 4 pairs; number of bars in commutator, 48.

We think the electrical world will agree with us, that the figures kindly supplied by Messrs. Ganz and Co. are among the most complete and most interesting that have ever been given concerning any dynamo. Figs. 20 and 21 give two views of this machine, and further illustrations will be given in another issue.

(To be continued.)

BRITISH ASSOCIATION, 1886.

The following paper, amongst others, was contributed to the late meeting of the British Association on various subjects connected with Electrolysis :—

ON THE CONDUCTIVITY OF MIXTURES OF AQUEOUS ACID SOLUTIONS.

BY DR. SVANTE ARRHENIUS, OF STOCKHOLM.

An abstract of a paper to appear in Wiedemann's *Annalen*, specially made by the author, and communicated through Oliver Lodge. The translation made by W. N. Shaw.

1. *Methods employed and previous authors.*—Hitherto only comparatively few experiments on the conductivity of mixtures of electrolytes have been made by Bouchotte,* Paalzow,† Bender,‡ and Klein§. These experiments have, moreover, led to no definite general results, mainly on account of the paucity of experimental data.

My experiments have been made at 25° C. in the chemical laboratory of the Polytechnic at Riga on Kohlrausch's well-known method, with the use of the telephone.

2. *Distribution of the water among solutions.*—When two electrolytes are dissolved in the same water two different views of the nature of the solution may be held: either *all* the water affects the one electrolyte as well as the other, or the water divides itself so that one part of it only affects the one electrolyte and only the remainder the other electrolyte. Experiments (by Ostwald) have been made with acetic acid and butyric acid. Normal solutions of these acids have conductivities respectively of 1·478 and 1·020. According to the second view the conductivity of the mixture will be $\frac{1}{2}$ (1·478 + 1·020). It was found to be 1·250 (instead of 1·249). According to the first view the mixture would have a conductivity equal to the sum of the conductivities of acetic acid of half normal strength (1·119), and of butyric acid of half the normal strength (0·853); this would give the conductivity of the mixture 1·972. Many such experiments were arranged, and all showed the superiority of the second view. All the experiments discussed in this paper also prove the soundness of this view. We shall consequently adopt this second view in what follows.

3. *Fundamental formula.*—If two electrolytes (in dilute aqueous solution) are mixed in the proportion of $m:n$, and if the conductivity of the one solution be a, and that of the other b, then the conductivity of the mixture will be $\frac{ma+nb}{m+n}$ if the solutions suffer no change in the mixing. This formula is the mathematical expression of the idea that the conductivity depends solely upon the number of electrolytic (active)

Digitized by Google

molecules per unit volume and on the friction of the ions in the solvent. This friction undergoes no appreciable change in dilute solutions.

4. *Consequences of the interchange of water in the mixture of solutions.*—When hydrochloric acid solution is diluted the number of electrolytic molecules increases but very little* (for the sake of simplicity we may assume that the number does not increase at all). When, however, a solution of acetic acid is diluted the number of electrolytic molecules is considerably increased (*e.g.*, by dilution to twice the volume from a normal solution the increase is in the ratio of 1·51 : 1). When, therefore, solutions of hydrochloric acid and acetic acid are mixed the conductivity will be greater than the above formula shows if water is transferred from the hydrochloric acid to the acetic acid solution, and *vice versâ*. In general when solutions of a stronger and a weaker acid are mixed, and the weaker acid takes water from the stronger, the conductivity will be greater than that given by the formula, and conversely if the stronger acid takes the water of solution from the weaker. A formula for this phenomenon is easily deduced; it shows that if the above consideration is valid the conductivities of the original solutions must not be very widely different; it likewise shows that the greatest deviations from the formula occur when the solutions are mixed in equal quantities.

5. *Isohydric solutions.*—If a given solution of an acid be mixed in equal volumes with solutions of another (stronger) acid of different degrees of concentration it is found that the above formula is applicable for a certain degree of concentration. For greater concentration negative deviations will be found, and on the other hand for less concentration positive deviations. According to the explanation given above, that solution of the second stronger acid, which possesses the particular degree of concentration, is of such a nature that it neither takes away water from the first solution nor gives any up to it when the two are mixed. On this ground I call in what follows two such solutions of different acids relatively *isohydric.* I have defined the concentrations of the solutions by their conductivities.

The experimental method for the determination of the conductivity of isohydric solutions will be most easily explained by means of an example.

To find the hydrochloric acid solution, which is isohydric with tartaric acid (75·51).† Under "observed" is placed the conductivity found, under "calculated," the conductivity calculated by the formula given.

	Obs.	Cal.	Diff.
5 cc. tartaric acid solution (75·51) + 5 cc. hydrochloric solution (94·62)	84·49 ...	85·07 ...	− 0·58
5 cc. tartaric acid solution + 5 cc. hydrochloric acid solution (85·68)	81·34 ...	80·60 ...	+ ·78

By interpolation (and allowing for the error of observation = 0·5 p.c.), we get as isohydric with the tartaric acid solution (75·51) the hydrochloric acid solution (89·2 ± 2·9). In a similar manner the numerical values contained in what follows have been obtained.

6. *Examination of the view adopted in* § 2.—This examination was conducted in two different ways: (*a*) *Solutions which are found to be isohydric when mixed in equal volumes must also be isohydric when they are mixed in other proportions.*

This proved to be the case. Phosphoric acid (223·7) and hydrochloric acid (167·4) were mixed in the ratios 3 : 1, 2 : 2, and 1 : 3; oxalic acid (4·947) and acetic acid (4·837) in the ratios 10 : 3, 1 : 1, and 3 : 10; tartaric acid (1·566) and hydrochloric acid (1·757) in the ratios 10 : 3, 1 : 1, and 3 : 10; acetic acid (12·18) and hydrochloric acid (14·54) in the ratios 10 : 1, 10 : 2, 10 : 4, 10 : 7, 1 : 1, 2 : 3, 1 : 2, 1 : 5, and 1 : 10. In no case was there a difference between the observed and calculated conductivities which reached the limit of the error of observation (0·5 p.c.)

(*b*) *Solutions which are isohydric with any the same solution must also be isohydric with each other.* Otherwise, as is easily seen, we might have three solutions, among which a permanent current of water would circulate always in the same direction. I have found—

A. (*α*) Phosphoric acid (225·6) isohydric with oxalic acid (139·7 ± 7·5).
,, ,, ,, ,, ,, hydrchlric acid (168·8 ± 10).
(*β*) Oxalic acid (141·7) ,, ,, ,, ,, (166·4).
B. (*α*) Hydrochloric acid (88·59) ,, ,, tartaric acid (75·00 ± 2·5).
,, ,, ,, ,, ,, oxalic acid (85·07 ± 3·5).
(*β*) Tartaric acid (75·39) ,, ,, ,, ,, (82·08 ± 3·3).
C. (*α*) Formic acid (5·576) ,, ,, ,, ,, (4·901).
,, ,, ,, ,, ,, hydrochloric acid (5·309).
(*β*) Oxalic acid (4·915 ± 0·17) ,, ,, ,, ,, (5·336 ± 0·13).

It will be seen that the numbers are perfectly satisfactory.

7. *Table of isohydric solutions.*—In the following table particulars of isohydric solutions of six acids, as different as possible, are collected; their conductivities (multiplied by 10^8) are given, together with the possible errors. Above the conductivities I have put in brackets the number of gramme-molecules per litre of the corresponding solutions. These are calculated from Ostwald's numbers. Solutions more concentrated than normal ones have not been investigated.

Hydrochloric acid.	Oxalic acid.	Phosphoric acid.	Tartaric acid.	Formic acid.	Acetic acid.
(0·1737) 609 ± 35	(0·513) 607				
(0·0461) 168·8 ± 10·0	(0·0625) 139·7 ± 7·5	(0·337) 225·6			
(0·0238) 88·6 ± 2·9	(0·0031) 85·1 ± 3·5	(0·0764) 82·2 ± 8·2	(0·520) 75·0		
(0·00475) 17·98 ± 0·46	(0·00488) 16·27 ± 0·46	(0·00702) 16·11 ± 0·72	(0·0260) 16·41 ± 0·45	(0·1077) 16·85 ± 0·64	(1·000) 13·81
(0·001402) 5·336 ± 0·134	(0·00135) 4·915 ± 0·175	(0·00163) 4·926 ± 0·174	(0·00324) 4·903 ± 0·146	(0·01261) 5·467 (± 0·15)	(0·0965) 4·855
(0·000349) 1·524 ± 0·032	(0·000396) 1·582 (± 0·05)	(0·000440) 1·479 ± 0·057	(0·000498) 1·499 ± 0·20		(0·009175) 1·476

8. Since obviously any solution of two acids in the same water can always be represented as two isohydric solutions, it follows that *when two acid solutions are mixed the two acids divide themselves with reference to the water, so that two isohydric solutions are formed.*

From the above table it follows that the specific conductivities of isohydric solutions are approximately equal.

Further considerations, which cannot here be given, show that if the conductivity of a mixture of acids is calculated on the assumption that solutions of equal conductivity are isohydric, the probable error amounts to 1 p.c., being rather greater if the strengths of the acids are very different, and less if they are nearly equal.

9. *Supplementary Remarks.*—The different bases have also been examined in a perfectly similar manner. The results obtained are strictly analogous, including the equality of the conductivities of isohydric solutions. However, the carbonic acid of the air had produced a disturbing effect to such an extent that the numbers are too uncertain for publication. I have also found that acetic acid (1·166) is isohydric with ammonium acetate (0·469). The ratio of the conductivities of the two (2·485 : 1) is nearly the same as the ratio of the maximum values of the conductivities of acids and salts (2·83 : 1 according to Kohlrausch). This seems to point to the conclusion that an electrolytic or active molecule of an acid (at ordinary temperature) in water conducts 2·83 times as well as an electrolytic molecule of a salt, and not that in extreme dilution the acids are, say, more loosely combined ("disgregirt") than the salts. This arises probably from a smaller friction of the ion H of the acid (probably also of the O H of the bases) with respect to the water, in which it also occurs as an ion, than occurs with the other ions. This difference might disappear at higher temperatures.

From the hypothesis that the different electrolytes divide the water between them there arise relations which promise to

* *i.e.* the molecular conductivity increases—I refer always here to dilute solutions.

† By this is understood tartaric acid of conductivity 75·51. The units here employed may be reduced to Kohlrausch's by multiplication by 10^{-8}.

Digitized by Google

explain some very curious phenomena. If, for example, a weak acid or base and a neutral salt are dissolved in water isohydric solutions will be found, in which the weak acid or base will get extremely little water. In consequence, its molecular conductivity, and accordingly the number of active molecules, will be very considerably diminished. I anticipated this on other grounds in my paper of 1884,* and endeavoured in that way to explain that the weak acids prove to be much weaker on mixing with bases than they are for the same concentration when no other bodies are in the same solution. The same hypothesis may also explain the great depreciation of strength of weak acids when neutral salts are present, as calculated from the rapidity of reactions,† and of the weaker bases in saponification reactions. I am still engaged upon the solution of similar questions.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

ADDRESS OF THE PRESIDENT, SIR CHARLES BRIGHT.

In addressing you at the first meeting of our new session, I wish in the first place to express my most cordial thanks for the honour conferred upon me in being elected to the office of President during the present year, the more so because it is a period specially interesting to us, as in it occurs the Jubilee of the Accession of our beloved Sovereign, and also of the first practical realisation of the electric telegraph. I am glad to be able to state that our society continues to flourish; and to maintain its justly acquired reputation for the value and utility of the papers read, and of the discussions upon them, which are often of more importance than even the papers themselves, as bringing forward views and information on diffe ent sides of the questions raised; and, while I refer to this, I wish to say that I should like to hear more, if possible, during the discussions in the course of this session from those who have not been so long in the society as some of us, and the only way to obtain this result is that those who join in the early part of any discussion should make their remarks as concise and as much to the point as possible, so that our juniors may have time left to speak. The total number of our members of all classes is now 1,343. At the first meeting, in February, 1872, it was only 110. At that meeting the President, referring to the *raison d'être* of the society, adverted to the impossibility of one great scientific body like the Royal Society succeeding in cultivating all the different departments of science in detail; and that therefore other societies, like the Astronomical, the Geological, the Chemical, or our own, were essential for their own especial fields of scientific knowledge and practice.

It is somewhat curious that Dr. Priestly had the same views when, so long as one hundred and twenty years ago, in the preface to his "History of Electricity," he suggested that an Electrical Society should be formed, to be devoted to electrical and kindred investigations. "The business of philosophy," he said, "is so multiplied that all the books of general philosophical transactions cannot be purchased by many persons or read by any person. It is high time to subdivide the business, that every man may have an opportunity of seeing everything that relates to his own favourite pursuit, and all the various branches of philosophy would find their account in this amicable separation. Let the youngest daughter of the sciences set the example to the rest, and show that she thinks herself considerable enough to make her appearance in the world without the company of her sisters." This suggestion of Dr. Priestly, made in the year 1767—long before galvanism, electro-magnetism, thermo-electricity, and magneto-electricity were known—bore no fruit, at all events not for many years. In June, 1837, however, a society was formed entitled the "London Electrical Society," of which Mr. Gassiot and Mr. Sturgeon were the principal founders, one becoming, subsequently, the treasurer, the other the first president. The name of the former will be well remembered for his researches in electricity, and for the liberal manner in which he constructed apparatus on a large scale for the purpose. The latter name suggests a long record of experiments, of which the most valuable was his discovery of magnetising bars of soft iron and rapidly changing their polarity by voltaic currents; in other words, the invention of soft iron electro-magnets, which are so largely used in telegraphs, telephones, and almost every kind of electrical appliance.‡

Mr. Sturgeon, the president of that society, in his inaugural address in October, 1837, claimed that "electricity was the most important experimental science ever cultivated by man," and remarked that the "preceding forty years had been more productive of electrical discovery than all the antecedent centuries embraced in the history of the science."§ Sturgeon was justified in his conclusion; for those forty years included the labours and discoveries of Volta, Brewster, Arago, Humboldt, Wollaston, Davy, Œrsted, Ampère, Schweigger, Ohm, Becquerel, and, above all, of Faraday, who was then in the midst of his ever memorable experiments. A number of papers, upon almost every branch of electrical science then known, were contributed to the *Proceedings* of the London Electrical Society, part of which were published in its *Transactions*, which will be found in our library, and the remainder in Sturgeon's "Annals of Electricity." The society however, lacked in vitality; there were in its best days only 76 members, and it was finally dissolved in a little less than six years. The late Mr. C. V. Walker, who was one of its members, having joined in April, 1838, told us, in his presidential address here, all about the decline and fall of that small society. He ultimately became both treasurer and secretary. As treasurer, in the culminating year of decay, he only received £77 with which to pay himself as secretary, for the printing and publishing of the *Proceedings* and all other expenses of the society. Now, our Society of Telegraph-Engineers and Electricians commenced its yearly accounts at the end of 1872, with subscriptions to the amount of £422. In *its* sixth year the treasurer received £1,275, of which £615 was expended in printing and issuing the society's valuable *Journal*. The income last year amounted to £1,818. The income of the society was, during the first years of its existence, almost exclusively derived, as it still is, to a very large extent, from the subscriptions of those who are more or less intimately associated with electric telegraphs, for although every other branch of applied electrical science is now well represented on the list of members, a large contingent of subscriptions still come from those engaged in the Postal Telegraphs, in the Indian Government Telegraphs, in the large submarine cable companies, and, in fact, from telegraphists spread over the face of the globe; others, again, from the large manufactories connected with the supply of telegraphic instruments, materials, cables, and their accessories. Our society might well use the motto of the Royal Engineer, "*Ubique*", or, let us say, "*Quæ regio in terris nostri non plena laboris.*"

A purely electrical society might perhaps have had more success than its predecessor, at the time when our society was established, but I doubt it; for, on investigating the practical applications of electricity for the general use of mankind during the last half century, we find that nearly the whole of the work done and capital invested has been connected with electric telegraphs, at all events until 1878, since when a material movement has taken place in the development of electric lighting and telephones. The earlier part of the present century was one of surpassing interest in the advance of electrical knowledge, and all the requirements for an electric telegraph were at hand: the voltaic battery, the electro magnet, the multiplying coil, the magnetic needle, together with the knowledge that, if suspended, it could be deflected by a galvanic current passing through a fixed coil adjacent to it; all were ready, and it is not to be wondered at that numerous devices for carrying on telegraphic communication by means of electricity were proposed and shown by many philosophers and experimentalists in different parts of the civilised world. Ampère himself proposed, on the suggestion of the illustrious La Place,* that a telegraph might be made with needles deflected in such a manner as to communicate different letters of the alphabet; and it was subsequently computed, at the trial of an American patent case, that more than sixty claims might be made out for suggestions of various kinds for an electric telegraph prior to its actual realisation. It is no part of my purpose to attempt to award the proportion of merit due to each or any of the long array of inventors. Hundreds of most promising discoveries have died an early death for lack of industry or perseverance to foster them. The man who begins by inventing, and afterwards struggles through every obstacle and with the greatest difficulty brings it into actual practice, outstrips, to my mind, him who is merely the *projector* of even the most ingenious invention which history records. A man of genius and perseverance, such as I have pictured, thus expressed himself some years later upon the subject:—"It the electric telegraph were to be described generally in a few words, how should it be described? Might it not be called an application of a few known principles by means of a few simple contrivances to produce a practical result, which the experiments of scientific men, although their attention had been directed to the subject for a long series of years, had failed to produce? The merits of the invention must therefore consist, to a very great degree at least, in the practical realisation of that which before had been an idea or an experiment."† The writer of the foregoing was Mr., afterwards Sir William, Cooke, an officer in the Madras Army, who returned from India on furlough in 1831. The Liverpool and Manchester Railway had been opened for public traffic a few months before, and had proved a great success, the receipts being what was then considered the enormous sum of £250 a day, or a little more than £90,000 per annum. This was derived from fares of 7s. 6d., and three trains running each way daily. The public were fully appreciative of the boundless advantages of this stupendous power, and the general interest in it was almost without parallel. Notions of speed and distance were still relative, but their meaning had been changed. New railways were announced from London to Birmingham, thence to Manchester, and in many other directions. Cooke was a man of great intelligence and scientific tastes, and the effect on the history of telegraphs produced by the interest which this altered state of locomotion awakened in his mind will be seen hereafter. A few years later, viz., in March, 1836, when at Heidelberg, he saw for the first time, at the lecture room of the professor of Natural Philosophy, one of those experiments to which I have referred as being frequently exhibited to illustrate the possibility of telegraphing to a distance by electricity; it was fitted up between the professor's study and the lecture room, and consisted of a pair of suspended needles and fixed coils much after the fashion of Ampère's idea suggested by La Place fifteen years before, which had, however, like many others, been unproductive of any useful result. Cooke was deeply impressed by this experiment, and with the conviction that electricity might be applied as an instantaneous means of communication for the working of the railway system then extending all

Digitized by Google

over England, as well as for Governmental and general purposes. So sanguine was he as to the success of his scheme that he at once abandoned his former pursuits and devoted himself exclusively to the practical realisation of an electric telegraph. Within three weeks he made his first telegraph, besides working out numerous supplementary details. In November, 1836, he showed to Mr. Faraday the apparatus which he had constructed in order to exhibit to the directors of the Liverpool and Manchester line. No grass had grown under his feet since the idea had flashed on his mind some months before at Heidelberg. He was still absorbed in the first notion which struck him, of associating his electric telegraph with the working of railways for their mutual "safety and economy."* Early in the next year he became acquainted with Prof. Wheatstone, who had been in the habit of showing, in his lecture room, the feasibility of telegraphing by electricity, using two galvanometers and a permutating keyboard, by which deflections of the magnetic needles could be exhibited.

There is no occasion here, or in any civilised country, to descant upon the great scientific attainments and achievements of Sir Charles Wheatstone, from his memorable experimental determination of the velocity of electricity, in 1834, to the remarkable recording telegraph apparatus perfected by him in later days with the skilful aid of our ingenious mechanical engineer, Mr. Stroh, a member of our council. The result of the two experiments becoming known to each other was that they soon after agreed to combine their inventions. A patent in their joint names was applied for, receiving the great seal on the 12th June, 1837. The specification of this, the first patent for electric telegraphs in any country, is very elaborately drawn up, occupying forty-six large printed pages and three large sets of drawings, showing the details of their inventions. It comprises a complete reciprocal telegraphic system, indicating instruments of several kinds, sending and receiving keys very much like some of those used even now, methods of supporting and insulating the conducting wires, alarums worked by relays, and means of ascertaining faults in the line-wire by the use of detectors. The wires were to be placed in troughs, being previously covered with cotton and a resinous cement, and with varnish of different colours for the several wires, so as to distinguish them in case of repairs being needed. It will be seen by the foregoing abstract, and still more by any one who will examine this highly interesting specification, that the joint patentees had considered in a most careful manner many of the requisites and contingencies of the work which they were about to undertake. I may add that in after years the validity of the patent was upheld in two cases of infringement. Soon after the patent was granted permission was given by the directors of the London and Birmingham Railway to lay down the wires between Euston-square and Camden Town Station; and by the latter part of July, 1837, the first practical realisation of the electric telegraph in its application to railway working was ready for trial. Late in the evening of the 25th of that month Mr. Cooke and Prof. Wheatstone stationed themselves—the one at Camden Town Station, the other at Euston-square. In order to try whether the instruments would work through considerable distances, some miles of wire along which the current had to pass (besides the wires in the open air) were suspended in the large carriage-house near the Euston-square terminus, making the length 19 miles. Several friends of the inventors were present at Camden Town, among others, Mr. Brunel and Mr. Stephenson. Prof. Wheatstone first spelt out a message, and, on Mr. Cooke quickly and clearly answering from Camden Town, the practical realisation was accomplished. "Never did I feel such a tumultuous sensation before," said the Professor, "as, when all alone in the still room, I heard the needles click, and as I spelled the words I felt all the magnitude of the invention now proved to be practical beyond cavil or dispute."† I myself well remember experiencing feelings somewhat akin to those of the Professor some 28 years ago, when on board the "Agamemnon," steaming slowly into Valentia Bay, finishing the laying of a telegraph cable two thousand miles long, which extended to Trinity Bay, Newfoundland, the greater part being under water two miles in depth. The apparatus used on that ever memorable occasion at Euston and Camden Town was the diamond-shaped dial instrument, with vertical needles on horizontal axes, described in the specification and shown in the drawings. The instrument required five wires, and it may be asked why should instruments like this have been employed when they had others needing but one? The reason was that the former called for no skill in sending and receiving the messages, each letter being expressed by a simple signal of two of the needles converging to a letter. With this the inventors could easily telegraph to each other, and railway *employés* could take up the work after them without any delay; but I doubt if either Cooke or Wheatstone could have spared the time at that period to become proficient in sending or receiving a telegraphic *code*. The wires, which were laid up in a rope and placed in a trough, did not cost much in the manner they were made, though good enough for the time and the short distance. Moreover, the battery power required was small, and its action in deflecting the vertical needles to one or the other side was very simple and certain.

Thenceforward the electric telegraph prospered without a check. Wires were laid down on the London and Blackwall, and on the Great Western line between Paddington and Slough, and elsewhere. At first it was used only for railway purposes, but afterwards despatches were transmitted for the public at 1s. a message (without reference to length), which was the first popular use of the telegraph in England or any other country. Its application soon became nearly as miscellaneous as now, affecting the highest and lowest in the land—now acquainting the Queen that Prince Albert was leaving Paddington for Windsor, now effecting the capture of thieves going down for business on an "Eton Montem Day." At one time sending the Queen's speech at Westminster for the benefit of the Royal borough, at another ordering whitebait from London, or inquiring about luggage left behind. All at once the country was awakened to the importance of this new means of communication by the result of the following message from Slough to London:—"A murder has just been committed at Salthill, and the suspected murderer was seen to take a first class ticket for London by the train which left at 7:42 p.m. He is in the garb of a Quaker, with a brown greatcoat on, which reaches nearly to his feet. He is in the last compartment of the second first-class carriage." A little difficulty arose in transmitting this message, for in the signals of the instruments v answered for u, and there was no q, so the word "Quaker" was spelt K W A K E R, which the operator at Paddington did not at first comprehend. However, the delay was not enough to prevent proper arrangements being made for Tawell's reception. On arriving at the Paddington Station, after mixing with the crowd for a short time, he got into an omnibus, the conductor of which was a policeman in plain clothes. Tawell, the Quaker, no doubt thought, as one passenger got in and another was put down, that his identity was getting better mixed each time. At last, reaching the Bank, he got out, paid his fare, and after crossing and recrossing London Bridge, and making many turns and doubles, he went to a lodging house in Scott's-yard, Cannon-street. He had scarcely entered the hall when the omnibus conductor opened the door, and asked him, "Havn't you just come from Slough?" "No," said he. He was of course arrested at once, and afterwards tried, found guilty, and executed. The effect of Tawell's capture was a greatly increased demand for the telegraph and a great extension of the system. Cooke, who, in his deed of partnership with Wheatstone in 1837, had reserved to himself the exclusive management of the invention and the sole control of the engineering department, found his labours prodigiously increased. To use the words of one who was with him at the time: "With his own eye and his own hand he directed all the operations in the actual erection of the first telegraphs; he literally lived, for the time being, upon the railway, making a railway carriage his shelter by day and his couch by night."* He still held fast to his original plan of allying the telegraph with the railway, which afforded a wayleave, protection, and speedy access for repair in case of defect in the wires; while the safety and efficiency, as well as economy in the working of the railway were supplied by the telegraph by signalling every train from station to station and telegraphing generally throughout the line concerning engines and rolling stock. In a book issued by him in 1842, entitled, "Telegraphic Railways," I was startled to find the following:—"To illustrate the practical working of these arrangements under extraordinary circumstances, I will now follow an *express*, and *therefore unexpected*, train in its course from Derby to Leicester." He then proceeds to describe the process of signalling it through its course. I have examined a "Bradshaw's Railway Companion" of the time and do not find any express, but only mail and ordinary trains. I think that an *extra* train was meant, for I find the expression used in the examination of Mr. Saunders, the Secretary of the Great Western Railway, on the 6th February, 1840, before a Parliamentary Committee† (among the members of which were Sir Robert Peel, Sir James Graham, Lord Stanley, and Mr. Labouchere, afterwards Lord Taunton). Mr. Saunders stated, in reply to Lord Granville Somerset, that the danger of collision in sending out an *extra* train, without a great interval of time being allowed between it and the ordinary trains, might be guarded against by the use of the telegraph. He also said, in reply to a previous question, that "it perfectly performs all the duty that was expected of it;" and, in reply to another question, "that it would simplify the working and diminish the stock of every description, whether of engines or carriages, besides ensuring greater punctuality; and, in cases of accident, to repair the injury with the least delay."

By the latter part of 1845 the double and single needle instruments were used everywhere, and the extent and ramifications of the telegraph had so enlarged that the time was ripe for connecting together the whole system, and forming a company for the general transmission of messages and news for the public throughout England and part of Scotland. In this part of the original scheme, Mr. Cooke was fortunate enough to obtain the co-operation of Mr. John Lewis Ricardo, M.P. for Stoke-upon-Trent and chairman of the North Staffordshire Railway, through the introduction of Mr. Bidder, who was then the engineer of the London and Blackwall Railway and other lines. Mr. Ricardo was a man of extraordinary sagacity and great energy. He became, and continued for many years to be, the chairman of the new corporation, which was styled the "Electric Telegraph Company." An Act of Parliament for incorporating the company was applied for in the Session of 1846. By this time, however, there were other competitors in the field. Mr. Edward Davy had taken out a patent in July, 1838, for a telegraph in which three wires were used, and metallic points attached to magnetic needles were caused to press upon, and so to make various groups of marks upon chemically prepared calico at the receiving end, the solution employed being hydriodate of potash and chloride of lime. The patent was bought by the Electric Telegraph Company, but never came into use. Other patents were also taken out in 1841, 1843, and 1845, for a type-printing, an indicating, and an electro-chemical copying telegraph, by Mr. Alexander Bain, of Edinburgh, a most fertile and ingenious inventor, who had previously devised an electric clock. Another type-printing machine was also patented at the end of 1845, as a communication from Mr. Royal E. House, of the United States, by Mr. Jacob Brett, of which his brother wrote, in 1858, that this instrument "incurred a sacrifice on my part of many thousand pounds, without any valuable result for general purposes."‡

The Electric Telegraph Company found on going to Parliament that

they were opposed by Mr. Bain, who declared in his petition that he had invented an electric printing telegraph, and had previously communicated his invention to Prof. Wheatstone. When it came to the Lords' Committee, the Duke of Beaufort, its chairman, told the company's counsel that they had better arrange with Mr. Bain, hinting rather plainly that their Bill might otherwise be thrown out. A compromise was accordingly arranged; the company got their Bill, and Bain got £12,000. His patents were transferred to the company, and he entered into an obligation to give the company the use of any further inventions. He was subsequently elected a director of the company. Bain's prolific genius was soon at work again, and in December, 1846, he patented his electro-chemical telegraph, which consisted of a train of clockwork at each end of the line. At the sending station a paper ribbon, about half-an-inch wide, perforated with holes representing the different letters of the alphabet, as required for the message to be sent, was drawn over a conducting cylinder in connection with the earth and under a metallic spring or style connected to a battery, the other pole of which was connected to the line wire. At the receiving station a paper ribbon, moistened with an acidulated solution of ferro-prussiate of potash, was in like manner drawn by the clockwork over a metallic cylinder connected to the earth, and under a metallic style connected to the line wire. The clockwork being set in motion, which was done by a current causing an electro-magnet to act upon a detent, the current passed through the circuit making a blue mark at the receiving end whenever the sending style passed over a perforation and came in contact with the cylinder, and leaving a corresponding blank when the sending style passed over the non-conducting paper between the perforations. The instruments worked with wonderful rapidity; the blue marks appearing to stream out from the recording style as if by magic, so that a number of operators were employed to each instrument to make the perforations in the sending paper, which was done by mechanism causing it to pass between rollers and under a punch—one hole formed a "dot," and three a "dash," of the Morse alphabet. An experiment was tried in Paris with this electro-chemical telegraph before M. Leverrier and Dr. Lardner, in which a message of 282 words was transmitted through a continuous wire 1,082 miles in length, consisting of two telegraph wires joined together at Lille, making 336 miles, and 746 miles of insulated silk-covered wires in coils. "A pen," says Dr. Lardner, "attached to the other end, immediately began to write the message on paper moved under it by a simple mechanism, and the entire message was written in full in the presence of the committee (each word being spelled completely and without abridgment) in fifty-two seconds, being at the average rate of five words and four-tenths per second. By this instrument, therefore, it is practicable to transmit intelligence to a distance of upwards of 1,000 miles, at the rate of 19,500 words per hour."* I myself often saw, in the year 1847, Bain's telegraph working at an astonishing speed between Manchester and London, and have never been able to understand the cause of its being abandoned. The only inconvenience was the occasional breakage of the damp paper when handled by the operator; but this was obviated later on by Bain having a disc of prepared paper, like a large filter paper, placed on a metallic plate of the same size, which revolved round its centre, the style having a slow motion from the centre to the edge of the disc, so that it described a spiral commencing at the centre and terminating at the edge.† In this way there was no occasion for the writer of the message to touch the paper. It will at once be seen that Bain's telegraph was the father of the beautiful and rapid automatic instrument of Sir C. Wheatstone and Mr. Stroh now used at the Post Office, the latest speed of working which, as I am informed by Mr. Preece, is 435 words per minute, or 115 words faster than Leverrier and Lardner's experiment with Bain's telegraph. This speed of more than 70 distinct currents passing through the line wire and the instrument in a single second of time calls to mind Juliet's

"Lightning, which doth cease to be
'Ere one can say it lightens."

Nevertheless, having regard to the amazing number of currents generated in a second by the armature of a dynamo-electric machine, running at a high speed, I could not say that the limit has been by any means reached with the automatic telegraph.

Let us now return to the Electric Telegraph Company after they had come to terms with Bain and obtained their Act of Incorporation. Foreseeing the possible and, indeed, the probable contingency of other telegraphs being brought forward, they set to work, under Ricardo's guidance, to convert Cooke's contracts with the railway companies from wayleaves into exclusive agreements for a long term, so as to keep any other telegraph from passing over the line. This sagacious policy was successfully carried out, especially in the case of the leading railways and those comprising the great trunk lines from London to the north and west. By their Act they had the power to lay pipes and wires under the streets of towns, and by the 1st January, 1848, the company opened offices for receiving and transmitting public messages in London, Birmingham, Manchester, Liverpool, and other important places, which could also communicate with the many smaller places and railway stations previously connected up. The only large towns not in communication with the central station in Lothbury were then Bath, Exeter, Plymouth, Brighton, Chatham, Oxford, and Preston.‡ The charges were, however, much too high. A message from London to Birmingham or Stafford cost $3\frac{9}{10}$d. per word; to Liverpool, Leeds, or Manchester $5\frac{1}{10}$d.; York, $5\frac{3}{4}$d.; Edinburgh, $7\frac{1}{2}$d.; Glasgow, $8\frac{3}{4}$d.; Derby, Norwich, Nottingham, or Yarmouth, $4\frac{1}{2}$d. Even a lawyer, under the influence of such a tariff, became suddenly endowed with a power of writing on any subject in a most laconic style, which in his office he would have conscientiously declared to be positively impossible. The progress of the Electric Telegraph Company was gradual, but never flagged. In 1850 it had 1,786 miles of line and 7,206 miles of wire; in 1860, 6,541 miles of line and 32,787 miles of wire, with 3,352 instruments; and in round figures, when Government contracted to purchase the telegraphs in 1868, 1,300 telegraph stations in Great Britain and Ireland, 10,000 miles of line, 50,000 miles of telegraphic wire, 8,000 sets of instruments, 3,000 skilled persons in its employ; three Continental cables under its control.*

The year 1850 was notable in the history of the company, because, owing to its high tariffs, a clamour arose for competition, and in that year Acts of Parliament were granted to the Magnetic Telegraph Company and to the British Electric Telegraph Company, which afterwards amalgamated under the name of the "British and Irish Magnetic Telegraph Company," generally known as the "Magnetic Company." I was engineer to the latter company; Mr. Edwin Clark at the time, and afterwards Mr. Latimer Clark, and following him Mr. Culley, filling the office of engineer to the Electric Company. My brother, Mr. Edward Bright, was manager, and in later years also engineer, of the Magnetic Company from its commencement to the Government purchase in 1870. Such of the railways in Great Britain as had not been exclusively secured by the Electric Company were eagerly arranged for by the new company, and nearly all in Ireland, which had not been then thought worth attention by the Electric Company. In this way competing lines were established on the Lancashire and Yorkshire, East Lancashire, Leeds Northern, Newcastle and Carlisle, Glasgow and South Western, and throughout Ireland. To connect up with London, the Magnetic Company laid a line of ten wires in troughs, along the high road by Birmingham to Manchester, continuing six wires to Preston, Carlisle, Dumfries, and Glasgow, with a fork from Dumfries to Portpatrick, for reasons which I shall soon give. On the other side of the Irish Channel another underground line was carried from Donaghadee to Belfast and Dublin, and an isolated branch from Cork to Queenstown. These underground wires were of No. 16 gauge copper, insulated by a continuous coating of gutta percha. This remarkable substance, which becomes soft and plastic when placed in hot water and capable of being moulded, hardening again on becoming cool, was first introduced to this country by Dr. Montgomerie, of the Indian Medical Service, who, observing that the Malays used it for making basins, jugs, shoes, and knife handles, inferred, from the crude native manufacture, that extensive uses would be found for it in Europe. He therefore purchased a quantity and sent it in 1843 to the Society of Arts in London. Its value was speedily recognised; many patents were taken out for its manufacture, and its applications soon became too numerous to catalogue. What concerns us is its qualities of being a good insulator of electricity, insoluble under water, capable of being laid over a wire by being passed through a die when hot, yet being pliable and to a certain extent hard when cold. Dr. Werner Siemens was probably the first (viz., in 1847) to use it for covering wires laid underground, but a further use of world-wide importance was soon to be found for it. Gutta percha covered wires came into use in the tunnel wires on railways in 1847, and soon after for the wires laid in iron pipes under the streets of towns. In January, 1849, Mr. C. V. Walker laid a length of two miles of No. 16 gauge copper wire, coated with gutta percha, in the English Channel, from the sands near the Pavilion Hotel at Folkestone, where the end was connected to the 83 miles of telegraph erected along the South Eastern Railway to London. The experiment was quite successful, messages being interchanged between the chairman of the company in London and Mr. Walker, on board the steamer "Princess Clementine," at sea, with the end of the gutta percha covered wire on board.† A plan had been previously matured by Prof. Wheatstone, as long before as 1840, for laying a submarine wire, covered with rope, between Dover and Calais, of which full particulars were given by Mr. Sabine in our *Proceedings*; but nothing came of it, and it was not until 1850 that the first telegraph message was sent across the Channel.‡ The late Mr. John Watkins Brett, to whom I have referred before in connection with House's type-printing telegraph, has justly been generally credited with the merit of having first taken this enterprise seriously in hand. So early as 1845, he was imbued with the conviction of a submarine telegraph being a possibility, and with his brother, Mr. Jacob Brett, registered on the 16th June in that year, a company for uniting Europe and America by submarine communication. He did not know of Prof. Wheatstone's channel project, concerning which he afterwards said: "Had these facts then been known to me, I cannot say how far they might have damped my determination to devote my whole time and means to establish and promote the submarine telegraph, and, if possible, to bring this country into instantaneous communication with India and America, then the sole object of my thoughts."§ An "oceanic line" was also included in his brother's patent for the printing instrument,‖ in which the wires were to be "coated with various colours to distinguish them." After obtaining permission from King Louis Philippe¶ in 1847, to unite England with France by a submarine cable, followed by a concession from Louis Napoleon, when President of the French Republic in 1849, a single copper wire, covered with gutta percha to the diameter of half an inch, was laid on August 28th, 1850, from Dover to Cape Grisnez, the greatest depth passed over being 30 fathoms. At every sixteenth part of a mile a leaden clamp or weight was securely fastened on to secure it in position. Messages were interchanged between the steamer "Goliath" and the English shore while the wire (which was coiled on a large drum) was being

laid, and afterwards between the two shores. Next morning, however, the circuit was broken, and it was found that the action of the waves had rubbed the wire upon the rocks, and destroyed the coating of gutta percha.

(To be continued.)

THE SELF-INDUCTION AND RESISTANCE OF COMPOUND CONDUCTORS.

BY LORD RAYLEIGH, D.C.L.

(Continued from page 172).

In view of the statement* "that the coefficient of mutual induction is less in iron than in copper wires," I may mention an experiment made with the aid of one of the compensators, in which the effect of the substitution of iron for copper is directly examined. The mutual induction measured is that between two circuits, one of which was composed of the two copper coils of 21 and 22 convolutions spoken of above connected in series; and the other of a single turn of wire situated midway between, and lying in a shallow scratch or groove on the wooden cylinder, by which its position was accurately defined. The arrangements being the same as in the determination of the constant of the compensator, the value of the double induction (obtained by reversal) between the circuit of a single turn of copper wire and the circuit of 43 turns was 40°·7. The single turn of copper wire was now replaced by a turn of iron wire of equal diameter and bedded in the same scratch, with the result that the double induction was 40°·6, the same value being obtained whether the iron wire were included in the primary circuit with the battery and interrupter, or in the secondary with the telephone. Care had, of course, to be exercised in the disposition of the leads, in consequence of the use of a single turn only for one of the circuits. So far as the experiment could show, the induction is absolutely the same, whether the single turn be of iron or of copper.

To return now to the bridge arrangement, the following are a few examples of the use of the original form of apparatus. The scale of the wire readings was in $\frac{1}{50}$ inch, the whole length (Q+R+S) being 1960. In ohms the resistance of the whole wire is 4·00. The interrupter was the "reed," making about 1050 (complete) vibrations per second. Thus

$$p = 2\pi \times 1050.$$

The first case is that of a helix of insulated copper wire, without core of any kind. To get a balance the compensator had to be placed at 54°, so that M = 36°, each degree representing 776 centim. The resistances also necessary were

$$Q = 610, \quad R = 190; \quad \text{therefore } S = 1160:$$

They are expressed in scale divisions, the value of each of which is

$$\frac{4{\cdot}00 \times 10^9}{1960} = 2{\cdot}04 \times 10^6 \frac{\text{centim.}}{\text{sec.}}.$$

If, as we are almost entitled to do, we assume that the resistance P to variable currents is the same as that readily found with use of steady currents, viz., 87·3 scale divisions, we may at once deduce

$$L = M\,\frac{P+Q+R+S}{S} = \frac{36 \times 776 \times 2833}{1160} = 68200 \text{ centim.}$$

We will, however, dispense with this assumption. Eliminating L between the two equations, we get for the determination of P,

$$P\left\{1 + \frac{p^2M^2}{S^2}\right\} = \frac{Q\,.\,R}{S}\left\{1 - \frac{p^2M^2(Q+R+S)}{S\,.\,Q\,.\,R}\right\}.$$

In the fractions containing M^2 the resistances must be expressed in absolute measure. We find

$$\frac{p^2M^1}{S^2} = \frac{4\pi^2 \times 1050^2 \times 36^2 \times 776^2}{1160^2 \times 10^{12} \times 2{\cdot}04^2} = {\cdot}0061;$$

$$\frac{p^2M^2\,(Q+R+S)}{S\,.\,Q\,.\,R} = \frac{4\pi^2 \times 1050^2 \times 36^2 \times 776^2 \times 1960}{1160 \times 610 \times 190 \times 10^{12} \times 2{\cdot}04^2} = {\cdot}1189;$$

so that

$$P = {\cdot}876\,\frac{Q\,.\,R}{S},$$

differing some 12 per cent. from the value (QR/S) given by the usual formula. Inserting the values of Q, R, S, we have

$$P = 87{\cdot}5 \text{ scale-divisions.}$$

This is the effective resistance to variable currents of the frequency in question.

With steady currents the readings were

$$Q = 557, \quad R = 190, \quad S = 1213;$$

so that

$$P_0 = \frac{557 \times 190}{1213} = 87{\cdot}3.$$

The resistance to variable currents, calculated by the correct formulæ with knowledge of the frequency of vibration, is thus almost identical with the value found with steady currents; whereas if we were to ignore the disturbance of the ordinary resistance rule by induction, we should erroneously conclude that the resistance to variable currents was some 12 per cent. higher than to steady currents.

Of other experiments made with this coil I will only mention one. When a stout copper rod was inserted, the circumferential secondary currents induced in it altered the readings with variable currents to

$$Q = 660, \ R = 190; \ M = 29\tfrac{1}{2}°.$$

The effective self-induction is evidently diminished, and the effective resistance increased in accordance with the universal rule*. The precise values may be obtained from our two fundamental equations, in the manner exemplified above.

If the foregoing experiment (with the copper core) be attempted with the scraping-contact interrupter, giving a mixed sound, no definite balance is obtainable.

The second example that I shall give is of a wire of soft iron about 1½ metre long and 3·3 millim. diameter. Here with variable currents from the reed-interrupter, of the same period as before,

$$Q = 178, \ R = 190, \ S = 1592; \ M = 8 \times 776 \text{ centim.};$$

from which we find

$$P = {\cdot}985\,\frac{Q\,.\,R}{S} = 20{\cdot}93 \text{ scale divisions.}$$

In the present case the ordinary simple rule (QR/S) would lead to an error of 1½ per cent. only.

The resistance to steady currents is given by

$$P_0 = \frac{100 \times 190}{1670} = 11{\cdot}38.$$

We may conclude that the effective resistance to variable currents of this frequency (1050) is 1·84 times the resistance to steady currents.

A long length of wire from the same hank was examined later by another method, and gave for the ratio in question 1·89.

In some of his experiments † Prof. Hughes found that it made but little difference to the self-induction of an iron wire, whether it was arranged as a compact coil of several turns, or as a single wide loop. The question is really examined with the present form of apparatus; for, since the resistance is not altered, the compensator readings give an accurate relative measure of the self-induction. A hank of nineteen convolutions of insulated soft iron wire required for balance 25°·8; but when opened out into a single (approximately circular) loop, the reading was only 11°·2, a much greater difference than that mentioned by Hughes.

A better experiment may be made with a coil of doubled wire. The length previously used was divided into halves, which were tied together closely with cotton thread and bent into a compact coil of 9 convolutions and about 4½in. diameter. When the two wires were connected in series, in such a manner that the direction of electric circulation was the same in both, the self-induction was represented by 24°·2; but when one wire was reversed, the self-induction fell to 9°·2, the

* *Proc.* Roy. Soc., Vol. XL. p. 468.

† *Proc.* Roy. Soc., Vol. XL p. 457.

Digitized by Google

large difference depending entirely upon the mutual induction between the two iron wires.

I had intended to apply this apparatus to investigate the self-induction of wires of various materials and diameters, formed into single circular loops, but the subject has been so ably treated by Prof. Weber as to render further work unnecessary, at least as regards the non-magnetic metals.

That the circle is the proper standard form for accurate measurement cannot be doubted; but the effect of magnetic quality is shown most markedly when the wires compared are of given length and diameter, and doubled so as to form single close loops. For a total length of $2l$ of copper wire, the self-induction is smallest when the wires are just in contact, and then*

$$L = 3{\cdot}772\, l.$$

In practice some interval is required for insulation, so that the coefficient of l may perhaps be taken to be 4. To iron wires the theory is not strictly applicable,† but we may probably assume without serious error

$$L = l\,(4 \log 2 + \mu) = l\,(2{\cdot}772 + \mu),$$

μ being the *permeability*. Prof. Hughes finds for the ratio of iron to copper under these circumstances 440 : 18‡; according to which we should have

$$\frac{3+\mu}{4} = \frac{40}{18},$$

or $\mu = 95$, in approximate agreement with values found by other methods.

Although the original apparatus of Hughes is capable of very good results, and is especially suitable when the wires under test are in but short lengths, the fact that induction and resistance are mixed up in the measurements is a decided drawback, if it be only because the readings require for their interpretation calculations not readily made upon the spot. The more obvious arrangement is one in which both the induction and resistance of the branch containing the subject under examination are in every case brought up to the given totals necessary for a balance. To carry this out conveniently we require to be able to add self-induction without altering resistance, and resistance without altering self-induction, and both in a measurable degree. The first demand is easily met. If we include in the circuit the *two* coils of an induction-compensator, connected in series, the self-induction of the whole can be varied in a known manner by rotating the smaller coil. For the self-induction of the instrument, used in this manner, may be regarded as made up of the constant self-inductions of the component coils taken separately, and of twice the positive or negative mutual induction between them. The first part, in consequence of its constancy, need not be regarded; and thus every degree (within the admissible range) may be taken as representing $2 \times 776{\cdot}3$, or 1552·6cm., of self-induction.

The introduction, or removal, of resistance without alteration of self-induction cannot well be carried out with rigour. But in most cases the object can be sufficiently attained with the aid of a resistance-slide of thin German-silver wire. It may be in the form of a nearly close loop, the parallel out-going and return parts being separated by a thin lath of wood. A spring of stout brass wire making contact with both parts short-circuits a greater or less length of the bight.

(To be continued.)

ELECTRIC STREET CARS.

In our issue of December 24th we gave an important paper upon this subject, which was read on the 7th ult. by Mr. Martin before the American Institute of Electrical Engineers. At the close of the paper the following discussion took place, which will be found to contain statements of considerable interest:—

Mr. J. Murray Mitchell: I rise for the purpose of corroborating what Mr. Martin has said in relation to the Baltimore road, and also to direct your attention, and I think, perhaps, also his, to the fact that in the comparison shown in his report between horse-power and electricity, the comparison of $6.50 to $4 is not as advantageous to electricity as it should be, because the average speed which is accomplished there with electricity is eight miles an hour, and the speed which they formerly had was only four miles an hour, which of course reduces the cost in comparison, so that the cost of electricity should be put at about $2, as against $6.50, instead of $4, as against $6.50.

Mr. J. Wetzler: Mr. Martin has remarked in his paper that one of the principal points to be considered was the coal bill. It is interesting, therefore, to note that in the Julien electric railway at Hamburg a calculation has recently been made on the basis of sixteen hundred kilometres run; that is equivalent to about one thousand miles. Mr. Huber, the engineer there, calculates that for one thousand miles run the energy required to propel the car one kilometre was, on the average, equal to three-fourths of a horse-power hour. Now, that figures out in this way—If it takes three-quarters of a horse-power an hour to propel a car one kilometre, and assuming that three pounds of coal per horse-power per hour is what a fair, average engine will do, then the energy or coal required to propel the car one mile would be three and a half pounds of coal per car mile. Now, take for instance, the Third-avenue road in New York. On a basis of three and a half pounds of coal required to propel a car a mile, we should have, assuming there were three hundred cars—I think Mr. Martin puts it at 360—say, then, there are sixty extra cars, which are either summer cars, or cars laid off for repairs, that would give 175 pounds of coal per car per day. I am basing that figure on a run of fifty miles per car per day. That would give 52,500 pounds of coal a day, or twenty-six and a quarter tons. Calculating a ton at three dollars, we should have for the coal bill alone per day only $78.75, and that is with accumulators. I think the company would be very willing to spend $78 for coal, if that will do it. That is what it figures out at.

The Chairman then called upon M. Julien, who spoke in French, his remarks being translated by Mr. C. O. Mailloux.

M. Julien said that the circumstances under which the tests were made at Antwerp were such that they represented almost an inimical feeling to the question of electrical traction by any process whatever. During the six months that the tests lasted every detail of the system was subjected to the closest scrutiny; the cells were sealed, and they were kept almost under lock and key, and he was scarcely allowed himself to look at them. The tests were made by judges, the most competent engineers and electricians, and were made with every precaution that might be necessary to prevent any tampering with the regular order of procedure. Referring to the statement made by Mr. Martin, and the assertion based on it made by Mr. Wetzler, that the expenditure of energy necessary for electrical traction is three-fourths of a horse-power hour per kilometre, and that as the energy required for the lamps must also be counted in, which he certainly thought would be ten cents a day, he calculated that the total expense of about two dollars a day per car would be necessary for the energy actually needed, and that counting an expense of two additional dollars for all other costs of maintenance, wear and tear, interest and various other expenditures, that we would arrive at the cost of four dollars which had been mentioned. M. Julien said that the cost was thus found by the experiments made at Antwerp, and that cost might be considered, so to speak, historical; that it might be conceded to be the cost on which they could safely calculate the probable expenditure of running the electrical car, with accumulators, on heavy traffic.

Mr. C. J. Van Depoele: I can simply corroborate what has been said. Still, there is one little plant that I might give the exact cost of, because the cost is about the main thing to be considered. We ran a plant in Minneapolis, Minn. This is, I believe, the largest electric railroad ever run in this country, or anywhere else, so far as I know. We have there about a sixty horse-power motor, and the train consists very often of ninety tons weight, or ninety-one tons. We have run it for about nine months. I might state also that they have tried a soda motor there, which I will tell about later. But at all events we have been running there at about an expense of 3,000lb. of coal a day—that is, starting to work at six o'clock and running till half-past eleven at night. Certainly, any of the locomotives that used to do the work before consumed as much as four tons of coal a day for the same work, which shows that although we have to transform our power twice, still we will have a great economy over the ordinary steam engine. Our system is not now running, for the simple reason that some other parties persuaded the authorities there that they were going to bring there for them to use something wonderful in the shape of a soda motor—a soda fountain with a stick in it, or something of that kind. The soda motors came, and we went off the track and let them on. But let me say those soda motors can hardly pull themselves, and at present are lying there like a lot of old scrap iron in the shops of the railroad. Of course the authorities there would not at the present time like to take back the electric motors for fear of stultifying themselves. But we ran very practically over the route, using only very common apparatus. The whole thing was only a common freight car with four ordinary 36in. wheels and an ordinary gearing from the motor to the countershaft and from the countershaft to the axle of the wheels and to the axles of the common car, wearing out only one belt in all that time and working eighteen hours a day, carrying forty-seven of their regular railroad trains a day. So it was shown that electricity can be used for heavy work as well as for light work.

Another instance in which figures might be given—of course all this figuring will come much easier after we have big plants running—is this: We are now putting up a big plant in Montgomery, Ala., where we have twelve cars running, and when all is finished we will be able to give the exact cost of running; but so far as we have tried it, and the grades are 6½ and 8 per cent. there—in fact, there is not a foot of level ground in Montgomery—with two cars we have consumed an average of nineteen

Digitized by Google

hundred pounds of coal a day, so that it cost but five and a half or six dollars a day with the two cars with the engineers' wages. This is a very small plant, and if small plants can do as well as that, larger plants can do much better.

Mr. C. O. MAILLOUX: There is a question which is now agitating the minds of practical engineers, and which gives me the opportunity to ask Mr. Van Depoele a question. It is this: There is a great deal of doubt, a great deal of difference of opinion, as to the manner in which the energy shall be applied to the shaft of the motive wheel—the driving wheels. I heard Mr. Van Depoele say that he gears his motor to a countershaft and that he conveys the motive power from that countershaft to the driving wheel by means of a link belt. Now that link belt is, I understand some to say, one of the bugbears of the electric railway, and I would like to ask Mr. Van Depoele about the length of time that that link belt has been running; also about how great a velocity it will stand safely. That is to say, how many feet per minute will it run without making too much noise or without being strained unduly; and, also, how long the link belt will last under those conditions?

Mr. VAN DEPOELE: I will be very glad to answer this question. We have some link belts running now for the last eight or nine months on street cars. We have tried several different modes of transmission to gear directly to the axle of the car, something which will obviate the vibrations transmitted by the axles running directly over the road. There at once we have a flexible connection between the motor and the car. The motor can stand on the same body of the car itself and consequently does not participate in the heavy vibration to which it would be subjected if it were carried directly by the axles of the wheels. Consequently, with street cars that is about the best connection I can find at present. I would have it understood, however, that any ordinary link belting in the market will not answer the purpose. We have a link belt which we had made for the purpose of our business. We have tried the cast iron link belt and found it to make considerable noise, and to wear out too fast, while it is not capable of running at a high speed. I have run at thirty miles an hour, and I did not myself formerly believe that a link belt could do the work, but it seems that when it is solid and correctly made you can run it at that speed without hurting it. The link belt used by us consists of two side pieces of steel pressed, and the steel bushing pieces are then fastened to a steel thimble at the upper end. Right through that steel thimble goes a pin, which catches the two lower ends of the next link, and consequently there is no friction in the small parts, it being confined to the larger surface of the thimble, right over which there is a steel roller. There is really no wear to the chain. We have had in Windsor, Canada, a chain running there for about eight months, and, in fact, it is just as good to-day as when first put down. The belt was then running at about the rate, I should judge, of one-third less than what the wheels were, or fully twenty miles an hour; and at the end of the track I stopped to feel whether the belt was hot, and it was not warm at all. Of course, for heavy work and fast speed, I think the link belt would not be suitable. Then you want to have a direct mode of connecting. Certainly it is very difficult to get a good connection between the motor and the axles of the wheels, because to make a motor large enough to connect directly with the axles of the wheels without any gearing, the motor has to be made too large. I think it would be out of the question to so construct it for ordinary speeds. But to gear back, of course, you have to use some kind of gearing. Friction gear I do not take much stock in. It is not reliable; it wears out, and there is always some trouble about it. Of course the cog-gear is positive, but it makes too much noise. But if you put up gear that is solid and mathematically true and with good lubrication I find there is not much noise when the gear is entirely covered up. We have the same gear in Scranton, which cannot be heard when running. It is well boxed and works well, and does not wear out and fits tightly, although how long it will last of course we do not know. We have several of them running, and they run well. If you gear back in the ratio of one to eight you will have a good deal of noise, at one to four you will hardly have any noise at all, at one to eight there will be considerable wear, at one to ten, of course, still more. There is a kind of medium between those, and you will have to take your choice in making your proportions; but the link belt, I believe, is the best thing for street cars to-day—that is, a belt made specially for the purpose.

Mr. G. W. MANSFIELD: I certainly would strengthen Mr. Van Depoele's remark that it is a most difficult and exceedingly troublesome thing to find any good method of connection between the motor and the driving wheels. He has spoken of a variety of methods of doing it, and there are other varieties yet of which he has not spoken. But one thing which he said, viz., that the link belt gave a flexible connection between the motor and the driving shaft, is an excellent plan, and, in fact, it would be necessary where you needed a flexible connection. But I would like to bring up just this one point, and that is that we have before us two distinct fields to labour in. One field is to equip the 20,000 cars already in this country, running over some three or four thousand miles of track and being drawn by some 125,000 horses, and with the system of construction which now prevails; and the street railroad men, of all men, I believe, are hunting not only for a means of propelling their cars, but they are also hunting for a better means and better mode of constructing their railroads. Now, with the present variety of construction of a large majority of the street railroads of this country you would need your flexible connection and possibly leather belts, perhaps the link belts; or possibly a good combination of gear can be arrived at to get this flexible connection. But the other field is the field of new construction, and this field is the one in which, I think, the electricians should specially labour. They should start now, and not wait five or ten years, but should educate the railroad profession and the street railroad men and the street railroad builders—the street car builders, rather —convincing them that their cars and that the street railroads must be built for electric motors. And if then they are built for the electric motors, we can supply them with something which is perfection, which will entirely do away with a great many evils which exist with horses and with every other means of drawing and propelling the cars, even with the cable. The cable has a limited field; it cannot operate branches successfully, and it has a variety of other evils which I will not speak of now. But with the electric methods in the construction of new roads, due to the marvellous flexibility of electrical application, there is no known or conceivable difficulty that electric motors and the application of electricity cannot successfully eradicate and overcome. So, then, I would merely give expression to this simple, modest thought, which the electric railroad men and the profession engaged in that work should impress upon the minds of all street railroad men, and all men interested in street railroads, viz., that their roads in future must be constructed from the very start for the application of electric motors, no matter by what system, but by the application of electricity. Then, I think, and by that means only, will we come to the general and successful application of the motors to every railroad throughout the country. It was at the meeting of the Electrical Section of the American Institute, that I gave an illustration, by means of diagrams, of the different kinds of methods which had been used, as far as I was familiar with them. I can only now repeat, if you desire, just those methods which I presented then, but I do not wish to discuss the efficacy of any single one of them. I said then that the most primal and the most perfect method obviously would be the application of the armature to the driving shaft direct. That does away with every particle of gearing. That method has been utilised by Mr. Daft in regard to a certain system more especially, and that is the Enos elevated system. The motor locomotive has two driving wheels and the armature shafts extend on each side of the driving wheels, the armatures being keyed directly on the shafts, and, of course, the periphery of the driving wheel is small. It is figured for a certain speed, twelve to fifteen miles an hour. The main difficulty which, I think, exists in using this direct gearing is simply a constructional one, on the electrical basis. The ordinary horse car wheel, if I remember rightly, goes only some ten or a dozen revolutions a minute to accomplish the ordinary speed which is used upon the tramways. Now, then, to construct a motor or an armature to go at that slow rate of revolution and develop any power, you would have to go to just the extreme which Mr. Van Depoele mentions and thus construct a *pretty* large motor. If you go into the electrical portion of it, you will see that you have got to get a certain length of wire upon your armature to get counter electromotive force and to do that at such a low rate of speed you have to construct a *rather* large machine, I think. Now, then, there is, next, a simple pinion upon the armature shaft, which runs in a large gear and is keyed upon the driving shaft. That method is simple, but it has its objections, although, if the mechanical details are properly carried out and well proportioned, even up to as high a ratio as eight to one or ten to one, I think that a very successful application can be made, and that is the application used on the Baltimore road. Worm gear can be used which is equally as simple as a pinion within a gear; it is equally as simple, but it is not as economical. The action of a worm in a gear is, we have always been told, a very brilliant method of losing power; that as high as thirty, forty, fifty, and even sixty per cent. of power is lost, due to the friction of the worm within the gear, although Mr. Reckenzaun, I believe, states that he has constructed a worm of a very high pitch, and has constructed his gear to match, and he gets a very low loss, 15 or 20 per cent., if I remember rightly, running in oil. Now, then, we go from that more simple process to another one, which is introducing one more subject, and that is a countershaft. Now, we can drive dynamos by a train of gears. We can drive from a pinion upon the armature shafts to a gear upon the countershaft, and then again from a small gear out of that upon a driving axle. Of course, any little difficulties which were apparent in the previous case would be increased in this case by the introduction of another gear. The noise could be cut down by using leather belting, and a variety of leather belts, round, flat, angular, and link belts. An innumerable number of forms of leather belting can be used which would take the rapid revolutions of the armature shaft and carry them to the countershaft with very little loss and with not much noise, and then the slower running countershaft with a pinion upon that, running the slow gear or slow driving axle, can then be employed very easily and with scarcely any noise and with very little wear. The flexibility, then, of this system would be between the armature shaft and the countershaft. Now, there can be a different modification of this, even, and I have noticed a description of one used by an inventor out West, in which he used a train of gears very similar to all the gears that are on the lathe in the ordinary machine shops. That is Prof. Henry's method, I believe. Now, that is the perfection of complication, and I do not know that I can go any further than to mention it in just this brief outline of the various ways which I am familiar with, that have been in practical operation. There is one other which I perhaps should mention in regard to a direct running with no intermediate gearing. I ought to have mentioned it first; it is that brought out by Mr. Stephen D. Field lately, and consists in using a crank shaft on the end of an armature shaft, which is attached to a connecting rod. That certainly does away with all intermediate gearing, and if he can successfully cut down the speed of the revolutions of his armatures to apply it to a street car, with all the street car difficulties of going so exceedingly slow as to keep pace with a mule that has two tons behind him and a very cross-grained disposition in front, and you have got to go just behind him and cannot go before him—if he can cut it down to that slow rate of speed, of course, for tramways, there could not be anything much better. But for lighter suburban roads, where you have got the right of way, and where you want to run at a rapid rate of speed, of course, then the direct application is superb.

Mr. S. D. FIELD: As to Mr. Mansfield's remarks, there are two ways to obtain the equivalent of speed of armature necessary. One is to confine

Digitized by Google

yourself to the ordinary two-pole machine, using an excessive number of armature turns; the other is to increase the number of poles of the machine. This I have accomplished and with only two brushes. Then, again, with regard to the conduits for city traffics, I propose, in introducing a street railroad on a line already established, to take out the sleeper bodily and put in its place a hollow cast iron girder, the top of which is capped with a steel rail with a flange carried underneath, giving a slot with a sharp angle to the street surface, so that you cannot get a horse's heel calk into it, but you can have your carrier in there. Mr. Martin said that this was the only way to carry very high potentials. I propose to carry 1,000 volts or more, but at the same time have the minimum strain on the insulators; that is, the insulating medium. To accomplish that I establish a power station at either end of the line, have two conductors insulated, and carry a zinc potential in one conductor and a copper potential in the other. Now, every car on such a line has exactly the same potential wherever it may be. By that means I can carry as high as a thousand volts on the line with great ease, and you have got to have this high electromotive force with a large number of cars and reasonably sized conductors. There is no other way to do it that I can see. Then for very large motors I wish to call your attention to a little improvement. You know how the things will spark unreasonably. I find that the spark is not governed by anything particularly. It seems to vary with the load, and with the machine, and with the man that works it. I thought I would let the spark govern itself. I have put a couple of brushes on the commutator at points of nominally equal potential on either side and connected them with an auxiliary motor called the brush governor. As long as these brushes are at the proper point no current will pass into them. But let them get ever so little out, and immediately the current commences to go through the auxiliary motor, which turns the brush holder to position of neutrality. The result has been very satisfactory.

THE ELECTRIC TELEGRAPH.

A lecture was delivered on the above subject on the evening of the 7th inst. by Mr. Thomas Moy before a meeting of the Balloon Society of Great Britain, the chair being taken by Mr. Hyde Clarke.

On the motion of Mr. W. H. Le Fevre, C.E., seconded by Gen. F. Brine, a resolution was passed at the outset of the proceedings, expressing the sincere sympathy of the meeting with Lady Bolton at the death of Col. Sir Francis Bolton, C.E., a member of the society, and the founder of the Society of Telegraph-Engineers and Electricians.

Mr. Moy then delivered his lecture, in the course of which he said:— This is to be a Jubilee year. We are going to do all sorts of wonderful things to impart renown to 1887, and our newspaper editors and others will boastfully write about the enormous progress of science during the latter half of the present century. But it may be wholesome to moderate our estimate of progress. As far as my experience has gone, I have found that the people of this country are very slow in making real progress, and very boastful when a persevering inventor has pushed his invention through the mountain of prejudice usually standing in his way; and that a man of progressive mind, or a genuine inventor, gets a great many kicks when living, and a little posthumous praise when dead. When railways were in their infancy fifty years ago, I well remember the insane and ruinous opposition to their construction. When railways were pronounced a success, and John Bull's prejudice had been overcome, then came the jubilant fit. And what is our position to-day, scientifically and progressively? We have learnt how to utilise a few of the materials around us. We have learnt to weigh, calculate, and estimate what is likely to happen if we put this and that together; but as to what the materials really are we are as much in the dark as ever. Up to this time, this year of Jubilee, we are compelled to admit, as Newton did, that we are but as children playing with pebbles on the sea shore, while the whole ocean of discovery lies before us. We live in the midst of mysteries, and because they have become familiar to us we forget that they are still mysteries, and one of those familiar mysteries is electricity, which, as it becomes developed, becomes still more mysterious. What is this which we call the electric fluid, for want of a better name? If you think upon the subject you must wonder what it can be. We have found out various means of producing it, and have turned it to account in many ways, but without ever finding out what it is. The electric telegraph, with its various appliances, has grown, and is the result of the labours of many minds. We cannot say that So-and-so was *the* inventor. It did not burst upon the world as a complete discovery. Six hundred years before the Christian era it was observed that when amber was subjected to friction it acquired the power of attracting and repelling light substances. This is, perhaps, the earliest record in existence. The next record is that Theophrastus, 300 years later, observed that a hard stone (supposed to to be tourmaline), when rubbed, attracted light articles. Pliny, in the year 70, and others, noticed the same phenomenon. But none of these men appear to have possessed genius enough to follow up the inquiry, and it remained very obscure until Dr. Gilbert, towards the close of the sixteenth century, published in his work, "De Magnete," a list of all those bodies possessing the same property. Having traced the researches of subsequent investigators, he continued: Prof. Wheatstone worked at the subject from 1834, and in 1836 his acquaintance with William Fothergill Cooke commenced, followed by a partnership, the result of such partnership soon being made apparent by their jointly patenting, on the 12th day of June, 1837, the first really practical scheme in electric telegraphy. It is due to these men to say that fifty years ago they gathered up the facts that then existed, put them together in a practical form, added to them many valuable arrangements of their own, and thus presented to the world that which will ever make their names renowned. The patent was, of course, followed by others, the results of further experiments and discoveries; but the filing of their application on the 12th June, 1837—only eight days before Her Majesty's accession to the throne—marks this year, not only as the Jubilee year of Her Majesty's reign, but also as the Jubilee year of the practical application of the electric telegraph. You will bear in mind that I do not call Cooke and Wheatstone the inventors of the electric telegraph; but I do claim for them that they first established a telegraph for practical purposes on a large scale. After noticing the valuable discovery of Steinheil, and observing that at the end of this half century of telegraphy there was very little that Faraday did not forecast, Mr. Moy said: In the year 1853, that which had been considered impossible was actually accomplished. I refer to the methods of telegraphing in opposite directions at the same time in a single wire. An Austrian gentleman, Dr. Gintl, was the first to solve this problem. Frischen, Siemens, and Halske followed with improvements. This advance was followed in 1855 by another Austrian gentleman, named Stark, who invented and carried out a method of sending two messages along a single wire, in the same direction, at the same time. In estimating and describing the force of electric currents, I think that electricians have made a great mistake, and the sooner it is remedied the better. I refer to such words as amperes, ohms, volts, and other terms taken from men's names, as descriptive of the amount of electric force. Suppose, in describing a steam engine, we were to say the steam pressure in the boiler is 140 "Trevethicks," instead of pounds; the vacuum is 27 "Watts," instead of inches of mercury; the power is 2,000 "Stephensons," instead of horse-power. Could anything be more out of taste? And yet all the talented electricians follow this clumsy and illogical apology for scientific terms. Having thus very imperfectly dotted down something like a general outline of the progress of the science, we see that at a very early period in the history of the science the idea existed of using electricity for telegraphic purposes; but all proposals for effecting it were wanting in simplicity and practical contrivance until Messrs. Cooke and Wheatstone, having succeeded in their experiments, patented their ideas and placed them before the world 50 years ago, in 1837. Since that time the telegraph has been extended enormously, and we can now "wire" to almost the whole of the habitable globe. But on land there is something immediate to be looked after. The recent inconveniences arising from the breaking of telegraph wires show that we have erected them on the assumption that fine weather must prevail all the year round. That the wires will bear the strain put upon them by supports a great distance apart in fine dry weather has been amply proved; but that they will give way during a snowstorm has been also amply proved. The remedy therefore seems likely to be found in shorter lengths of stretch; in underground wires or in some new arrangement. Now, underground wires are expensive, and when a fault occurs it is troublesome to find its position; and other objections are urged. I would therefore throw out the hint that it is possible a middle course could be found in towns by suspending the wires at about, say 20ft. from the ground, with ornamental supports attached to the houses. The railway companies will also have to put up more numerous supports, or adopt the underground system. During the last 50 years many men of talent have come to the front with their ingenious inventions relating to electricity, and at the present time a whole army of intellectual men are working hard in order to increase the usefulness, cheapen the production, utilise the by-products, and discover new sources of electricity. After referring to the experiments in connection with the electric light, the lecturer said: Now, I think I must have exhausted your patience, if I have not the subject. We have been considering *one* of the mighty forces of nature, one of the invisible things of the Creator. We have, as it were, just touched the "fringe" of this force. We have glanced at the last 50 years of its practical application. What will the next 50 years bring forth in the further development of this power? Who would have dreamed 2,400 years ago, when the first piece of amber was rubbed, that that would lead to what we see to-day? Who can say that there are not other forces in the world, the existence of which is as yet undreamed of, which will be discovered in the next 50 years, and become absolute necessities to mankind? I think it will some day be discovered that gravitation is closely allied to electricity and magnetism, and, if I may venture to put the idea before you, it may be that the revolutions of the planets are analogous to the action of dynamos, and that the various fields and currents in which the planets revolve, and by which they are interlaced, may possibly produce that mysterious force which we call gravitation. When I contemplate the great forces of nature, and our utter ignorance of what they consist, I not only think of Sir Isaac Newton's celebrated saying, already quoted; but I go further than that, and ask myself, Are three score and ten years to be the limit of man's existence, and is there to be no future development of our powers, our knowledge, our investigations, our appreciation of real good? And the inevitable answer comes, trumpet-tongued, "No!" A thousand things contradict the possibility of such a result; for to quote again from another author, "God hath set eternity in man's heart," and nothing less can satisfy his reasonable aspirations. The lecturer resumed his seat amid applause, with which his remarks had been frequently greeted.

The Chairman then said he presumed he had been invited to preside as one of the few survivors of the old telegraphists of that period from which Mr. Moy had dated the jubilee. His own branch of investigation had been acoustic telegraphy, in which he followed Mr. Wheatstone, of whose early career he gave some account from actual knowledge. Mr. Wheatstone's preference was for acoustic telegraphy, and in the early period the electric system was looked upon as cumbrous and expensive, and one system exhibited in working at the Polytechnic Institution by Mr. Francis Whishaw was the hydrostatic. On Mr. Wheatstone engaging in electric telegraphy with Mr. Cooke, that plan was brought into practical effect, and there was an end of acoustic telegraphy and hydrostatic. They had to throw their old studies on one side and adhere to the acknowledged electric system. In science, however, what was

Digitized by Google

really of value was never ultimately lost, and, if superseded by some other expedient, yet it might happen by that very expedient to be restored. Acoustic telegraphy being accounted dead, it was by the progress and development of the electric plan made more practicable, and under Graham Bell, Edison, Hughes, and others was brought into practical use in our days as the telephone. Francis Whishaw, the real originator of the great Exhibition of 1851, was obliged to enlist in the science of electric telegraphy. He (Mr. Clarke) was his colleague in making the final report on the electric telegraph for India, for the Hon. East India Company, and also on code arrangements for the Electric Telegraph Company here. The powers of the original costly apparatus were limited, and it appeared to be an object of primary importance to economise its use. Hence Mr. Whishaw was a great advocate of the code system as a means of transmitting more words with the same number of signals. On land lines the code is now of less value, on account of the rapidity gained by the duplex and multiplex telegraphy. On submarine systems, however, codes are extensively employed as a method for economising charges for messages. Whishaw was engaged at one time in adapting acoustic appliances for offices, particularly speaking tubes, and to one instrument he gave the name of telephone. At the early period described by Mr. Moy, the number of telegraph inventors here was very few; they could be counted, for there were few who had a definite idea of telegraphy, or looked upon it as a remunerative pursuit. His own appreciation of the value of such communicators was founded on the knowledge of the system of semaphores he had seen on the Continent, as established by Napoleon. That great administrator worked the semaphore from shore to shore throughout the bounds of his empire, and it was one of his great engines of government. It is, however, very difficult to prophecy as to the availability or impracticability of any matter of invention. Fifty years ago the number of inventors and investigators in this country was few; there was now probably an army of 5,000 inventors, investigators, and patentees in this country, and as many in the United States, each daily trying to get beyond the other. Hence, when any new discovery was made other applications extended or surpassed it. The effect economically was very remarkable, and likewise what was impracticable financially to-day was made feasible to-morrow. Those who remembered the experimental telegraph from Paddington to Slough which effected the arrest of Tawell, the Quaker murderer, would never forget how they were impressed by its rapidity of communication. A circumstance not less memorable was the rapid economy of cost. The first apparatus had a number of separate wires for signal letters, with an equal number of return wires. When the extension was projected it was considered these could be reduced to seven, with seven return wires. The seven were brought down to less; but during this time the earth circuit was found available and the return wires abolished. From three the wires were diminished to two. In the final result the number of wires and the cost were reduced to one-tenth. He himself remembered that while engaged on a submarine cable negotiation for Lisbon the cost of cables became reduced to a quarter, or from 100 to 25. In his own opinion, a great economy was yet to be effected in the cost of construction and laying of ocean cables. If invention and ingenuity effected great things, it was not always the inventor or the public who derived the benefit. In the case of that ingenious and able inventor, Alexander Bain, his patents were bought up by the Electric Telegraph Company at their own prices, and not used, in order to keep rival companies from employing them. If reward in a man's lifetime was by no means secure, still less certain was the poor heritage of posthumous fame, for which disappointed genius ever hoped. He hoped that the paper which had been read would be accepted in its proper light, as proposing a Jubilee, and that the Jubilee would be attended with practical results, and not be confined to a mere celebration.

On the motion of Mr. J. FitzGerald, seconded by General Brine, a resolution was passed, calling attention to the unsafe condition of electric communication in this country by overhead wires, and expressing the hope that members of Parliament would call on the Government to take measures to prevent the recurrence of the recent alarming disarrangements.

A vote of thanks to the lecturer brought the meeting to a close.

COMPANIES' REPORTS.

The Eastern Telegraph Company (Limited).

Report and accounts of the Directors for the half-year ended 30th September, 1886, to be presented to the twenty-ninth half-yearly ordinary general meeting, to be held at Winchester House, 50, Old Broad-street, E C., on the 20th inst., at 1 o'clock:—

The revenue for the period amounted to £292,229. 17s. 8d., from which are deducted £81,025. 9s. 10d. for the ordinary expenses, and £53,965. 5s. 5d. for expenditure relating to repairs and renewals of cables, &c., during the half-year. After providing £4,677. 3s. for income-tax, there remains a balance of £152,561. 19s. 5d., to which is added £4,079. 2s. 8d. brought from the preceding half-year, making a total available balance of £156,641. 2s. 1d. From this balance there have been paid—

	£	s.	d.
Interest on debentures and debenture stock	23,252	8	2
Dividend on preference shares	20,296	15	9
Two interim dividends of 1¼ per cent. each on ordinary shares	95 000	0	0
	£143,549	3	11

Leaving a balance of £13,091. 18s. 2d. which is carried forward to the next account. The revenue includes £16,600 dividend for the half-year upon the Company's shares in the Eastern and South African Telegraph Company, and also £3,570. 10s. net receipts for the half-year on the shares of the Black Sea Telegraph Company belonging to this Company. The cables of these companies are in good working order. The present accounts include the receipts for three months' working under the reduced tariffs fixed at the International Telegraph Conference in Berlin last year. The several sections of this Company's cables and the land lines in connection therewith are in good working order. The outlay in connection with repairs and renewals has been exceptionally large for the past half-year, mainly due to renewals of the Direct Lisbon line, upon which 191 knots of new cable have been used. Three-fourths of this cable have now been renewed out of revenue. The establishment of telegraphic communication with the British possessions on the West Coast of Africa by the African Direct Company was completed in September last. It is as yet too early to ascertain the probable traffic over the lines. In accordance with the provisions of the Articles of Association, two of the directors, George Garden Nicol, Esq., and John Denison Pender, Esq., retire by rotation at this meeting, and, being eligible, offer themselves for re-election. The auditors, Mr. Henry Dever, and Messrs. Quilter, Ball, and Co., retire, and offer themselves for re-election.

The Direct United States Cable Company (Limited).

Report of the Directors for the six months ended 31st December, 1886, to be presented at the nineteenth ordinary general meeting of the Company, to be held at Winchester House, 50, Old Broad-street, E.C., on Friday, the 21st inst., at 2 p.m.:—

The revenue for the half-year, after deducting out-payments, amounted to £19,603. 6s. 11d., against £38,115. 3s. 5d. (after similar deductions) for the corresponding period of 1885, being a difference of £18,511. 16s. 6d., against the half-year under review, owing to the reduced tariff referred to in the last report, the competition and low rates still continuing. The working and other expenses for the same period, including income-tax, &c., but exclusive of cost of repairs of cables, amounted to £16,354. 7s. 6d., leaving a balance of £3,248. 19s. 5d. as the net profit of the half-year, making with £3,050. 19s. 3d. brought forward from the previous half-year, a total balance of £6,299. 18s. 8d. For the corresponding half-year of 1885 the working expenses and other payments amounted to £16,631. 13s. 0d. An interim dividend of 2s. per share for the quarter ending September 30th, 1886, was paid on the 30th October, 1886. It is now proposed to pay for the quarter ending 31st December, 1886, a further interim dividend at the same amount per share; for this purpose recourse will be had to the reserve fund. A break occurred in the short section of cable on the 3rd August last, and was repaired on the 7th of September.

NOTES.

Exhibition of Telephony at Brussels.—This exhibition was opened to the public on the 14th inst. The number of exhibitors does not exceed thirty; but some interesting results will probably be forthcoming.

Fontainebleau.—A company has been floated in Paris for the introduction of electric lighting at Fontainebleau. Gaulard-Gibbs transformers are to be employed. 169 subscribers for 1,750 lamps have already been secured.

West India and Panama Telegraph Company.—The estimated traffic receipts of this company for the half-month ended the 15th January are £2,955, as compared with £2,639 in the corresponding period of 1886.

"Electricity and its Uses."—We have received from the Religious Tract Society a copy of the second edition of "Electricity and its Uses," by J. Munro, which has been revised and enlarged since its first appearance.

Sale of Varley Patents.—In our advertising columns particulars will be found as to the sale by private tender of the patents held by the Varley Electric Patents Proprietary (Limited), pursuant to an order of the Court of Chancery.

Tenders for Telegraph Material.—The Great Indian Peninsula Railway Company require tenders for telegraph materials. Specifications may be obtained on application at the Company's offices, 3, New Broad-street, E.C., and must be returned before the 30th inst.

The New Telephone Company.—The New Telephone Company has just carried out two private lines, each 6½ miles in length, between Margate and Ramsgate. The wires were erected by Mr. W. Covington, of Canterbury. The "Valve" instruments now appear to give perfection satisfaction.

Sale of Plant at the Colonial and Indian Exhibition.—We would remind our readers of the important sale, by Messrs. Wheatley Kirk, Price and Goulty, of engines, boilers, dynamos, and other electrical plant used at the Colonial and Indian Exhibition, which takes place on Wednesday and Thursday next.

The Post Office Telegraphs.—On Monday, the 17th inst., a notice was issued by the Post Office cancelling all previous notices as to delay in the telegraph service owing to the breakdown occasioned by the storm of Dec. 26th. The repairs have thus been completed in the space of three weeks. The telephone service in the metropolis is still in a disorganised condition.

Underground Wires in Germany.—The Berlin correspondent of *The Times* has received an official communication from the Minister of Posts and Telegraphs, asking him to state that fully one-half of the commercial messages pass over the underground wires in Germany, and that the scheme was originally planned from a commercial, and only in a secondary sense from a military point of view.

Globe Telegraph and Trust Company.—The directors of this company have declared the payment of an interim dividend on and after the 27th inst. of 3s. per share on the preference shares, less income-tax, and of 6d. per share on the ordinary shares, income-tax having already been deducted, for the quarter ended the 18th January. The transfer books will be closed from the 20th to the 27th inst., both days inclusive.

Amateur Photography at Telegraph Stations.—Messrs. G. M. Baines and S. S. Henry, of the Eastern Telegraph Company's station, Carcavellos, Portugal, have had the honour of photographing His Majesty the King of Portugal, Don Carlos, and Princess Amelia, whilst on a shooting expedition to that neighbourhood. The royal group was a great success, and does great credit to the operators, who have only practised the art during the past year.

King's College, London.—Prof. W. Grylls Adams, F.R.S., will deliver a course of lectures on magnetism, dynamic electricity, and electro-magnetism, and their applications to dynamo-machinery, electric lighting, transmission of power, &c., during the present session. A course of practical work in electrical testing and measurement with especial reference to electrical engineering will also be carried on under his direction in the Wheatstone laboratory. The lectures will be given once a week—on Mondays at 2 p.m.—and the laboratory will be open daily from 1 to 4, except on Saturdays.

Costly Economy.—In sending telegrams by the word rate, especially cable messages, it is possible to push economy too far. A lady of American ancestry, who is well known in certain circles, was recently suffering from severe illness. Some of her nearest relatives in New York cabled that if she was no better they would come over at once. The answer came "no better." On their arrival eight days later their feelings must have been of a somewhat conflicting character on finding the invalid entertaining a party of guests. The omission of a comma thus caused no end of expense, anxiety, and trouble.

Obituary.—We regret to announce the death of M. Ed. Blavier, Inspector-General of French Telegraphs, and Director of the School of Telegraphy at Paris. M. Blavier was also president of the "Commission on Improvements" attached to the office of the Minister of Posts and Telegraphs, and editor of the *Annales Télégraphiques*. M. Blavier has done a great deal of useful work in connection with French telegraphs, and as an electrician was one of the safest men in that country. His name is best known to English electricians in connection with a valuable modification of the "loop test" for determining the position of a fault in cable testing.

The Society of Telegraph-Engineers and Electricians. The first meeting of this society for the present session was held on Thursday, Jan. 13, at the Institute of Civil Engineers, Westminster, when the newly-elected president, Sir Charles Bright, delivered his inaugural address (the publication of which was commenced in our last issue, and is concluded this week). Previous to the delivery of Sir Charles's address a vote of condolence with Lady Bolton on her recent bereavement was carried. Prof. Forbes then moved and Mr. W. H. Preece seconded a vote of thanks to Prof. Hughes, the retiring president, to which Prof. Hughes briefly responded. The next meeting of the Society will be held on Thursday, 27th inst., at 8 p.m., when a paper on "Telephonic Investigations" will be read by Prof. Silvanus Thompson, B.A., D.Sc., member.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ended January 14th were £3,719, after deducting the fifth of the gross receipts payable to The London Platino Brazilian Telegraph Co. The directors have decided to change the company's financial year from October to September, to January and December, in accordance with the more general rule, and in correspondence with the Brazilian Submarine Telegraph Company, with which this company has working agreements. The next account, therefore, will embrace a period of fifteen months—viz., from October 1st, 1885, to 31st December, 1886. The annual meeting of the company will not be held this month, but as speedily thereafter as the

Digitized by Google

accounts can be prepared, which it is hoped will be in February.

IRON *v.* WOODEN TELEPHONE POLES.—The behaviour of the iron poles during the recent storms has somewhat disappointed the expectations of telephone and telegraph engineers, and has at least shown that the structures at present in use are of too flimsy a character for the strains which they may be called upon to undergo. It is a remarkable fact that during the last three weeks scores of cases have been visible in the metropolis where the iron poles have been bent and twisted into the most extraordinary forms, while the wires themselves have given way only on one side. On the top of a house at the southern end of Waterloo Bridge may still be seen a pole some thirty or forty feet in height, the upper half of which is bent very nearly ninety degrees out of the perpendicular. In this case the span upon one side is of great length, and the wires descend to a much lower level. In other cases the iron poles have snapped off short close to their bases. It thus appears doubtful whether the maximum economy is on the side of iron or wooden poles.

BRADFORD.—At a recent meeting of the Bradford Town Council, the Chairman of the Lighting Committee spoke as follows:—As to the supply of the electric light, he was aware that there were many applications to have premises lighted with electricity, and Messrs. Schmidt, Douglas and Co., had fitted up premises in the centre of a block of property from which they were able to supply shopkeepers in Kirkgate and Ivegate with the electric light. Hitherto the attitude of the Corporation had not been to encourage enterprise of this nature, nor had they done anything towards exercising the powers possessed by the Corporation in reference to the electric light. This was a "dog-in-the-manger" policy which, he thought, the Corporation ought not to persist in, but that either the electric light should be provided by the Corporation, or that others should be allowed to provide it. Holding this opinion, he had brought the matter before a meeting of the committee, but the consideration of it had been adjourned pending the settlement of some questions which had been submitted to the Board of Trade. When the committee again met this question would be decided, and they would, no doubt, either allow private firms, on payment of a royalty, to supply the electric light, or the Corporation would put down a plant of their own to supply it.

ELECTRIC LIGHTING AND THE GAS INTEREST IN THE STATES.—The following paragraph occurs in a review of the past year by the *Electrical World* of New York:—"Regarding the commercial progress of electric lighting during the last twelve months, the record of the work of the various companies engaged in it shows that it was marked with unprecedented activity, which will, I think, be continued. An interesting and, in many respects, important feature manifested during the year is the newborn friendship of the gas companies towards electric lighting. After years of bitter denunciation, they have at last recognised that the electric light has come to stay, and that if they would continue receiving their share of public patronage, they must furnish the electric light. Hence it has become a wide-spread practice for gas companies to apply for a change in their charters so as to enable them to furnish electric light in addition to gas. As yet this applies principally to the arc light, but it seems not improbable that the incandescent will soon also find favour with gas companies. We may, indeed, chronicle decided progress in this direction when, as has lately been the case, even journals devoted to the gas interests openly advocate the adoption of the electric light by the companies concerned." Another American journal contains a list of twelve gas companies who have recently filed petitions to be allowed to go into the electric lighting business.

ELECTRIC WELDING—A CURIOUS STORY.—Some few months ago, shortly after the announcement of Prof. Elihu Thomson's method of electric welding, various paragraphs appeared in the French papers hinting that very remarkable results in the same direction had been obtained in the laboratories at Creil. The germ of the invention was attributed to some Russian *savants* whose names were not given, but it was stated that they had received valuable assistance in the development of their ideas from the French electricians. The highly remarkable nature of this invention may be estimated from the statement that it was anticipated that the plates of an ironclad might henceforth be riveted under water. The actual facts of the case are now related in the *Bulletin International*, from which it appears that in the summer of last year a syndicate of Paris bankers sent a representative to study the Russian oil wells. While in St. Petersburg this gentleman met with certain individuals who succeeded in impressing upon him the importance of effecting the distillation of the crude oil in non-riveted boilers, and who stated that they were in possession of an electrical method which enabled them to construct such boilers. On the payment of a considerable sum down in cash, they consented to accompany the envoy to Paris, and preparations were made (at the cost of the Paris bankers) for experiments upon a large scale at Creil. These experiments ended in total failure.

THE BERLIN EDISON COMPANY.—According to *Industries*, the Berlin Edison Company have in their manufacture of glow lamps abandoned the old form of bamboo filament, and employ at present round carbon threads, treating them in the flashing plan, as is done in England. Messrs. S. Siemens and Halske also make similar lamps under licence. The company claim a life of about a thousand hours with an expenditure of energy of 3·3 to 3·6 watts per standard candle, and they are now turning out lamps at the rate of about a thousand per day, which, however, is barely sufficient for the requirements throughout Germany. Very few lamps of other types are seen in the larger Berlin installations. The Edison Company have hitherto been obliged to buy their dynamo machines from Messrs. Siemens and Halske, but with the first of this month the old agreement expired, and they are now free to obtain their dynamos from any other maker, or to build them in their own works. The latter policy will be adopted, all the preparations for the manufacture of dynamos having already been made, and their manufacture will be commenced as soon as the Board have given their formal sanction. The company have already experimentally manufactured various types of dynamos, and amongst these one with single horseshoe magnet placed vertically with the yoke in the bed-plate and the armature above, similar in arrangement to the machines made now by Gramme, Kapp, and Siemens. The company have also made arrangements for manufacturing plating machines.

A (REALLY) NEW TELEPHONE TRANSMITTER.—The remarkable results which were obtained by Prof. Hughes in his researches on superposed magnetism have not hitherto borne fruit in practice. It will be remembered that, at a meeting of the Society of Telegraph-Engineers in the year 1883, Prof. Hughes exhibited some steel magnets, consisting of four or more separate wires or strands held together at either end by a brass collar. These compound bars exhibited not the least trace of external magnetism until they were bent or twisted in the hands, when strong polarity was immediately mani-

Digitized by Google

fested. By reversing the direction of the twist the poles were simultaneously reversed. We do not know whether Mr. W. J. Morton, of New York, has based his telephone transmitter upon these researches of Prof. Hughes, or whether he has independently discovered the peculiar properties acquired by steel which has been repeatedly magnetised with equal strengths in reversed directions. Mr. Morton's transmitter consists merely of a coil of wire and a steel diaphragm which has received superposed magnetism. Now, this diaphragm, according to the inventor, does not act by bodily to-and-fro vibration, but by the disturbance of magnetic equilibrium which results from the molecular vibrations which are caused by the sound waves. It would, however, be difficult to maintain that the diaphragm does not execute vibration in the usual sense, and it seems to us more probable that the two effects are conjoined. We obtain our description of this instrument from the *Electrical World* of New York. Whether the results are sufficiently powerful for practical purposes we are not told. The instrument may obviously be used more or less efficiently as a receiver.

AS OTHERS SEE US.—The following remarks occur in the course of a retrospect of the past year in the columns of the *Gas World*. Although the opinion expressed in the latter part of the extract is couched in terms far stronger than we should care to endorse, or are, indeed, in any sense justified by the facts, yet the warning may not perhaps be altogether superfluous:—"The tendency towards perfection in gas-lighting has not been so rapid as in electric lighting, but it must be borne in mind that the early controllers of the gas industry had to feel their way. They had to deal with forces the nature of which was imperfectly understood, and it was only when the chemist and the physicist came to the aid of the engineer that the industry began to bud and to blossom, and ultimately to develop into its present magnitude. True, the electrician has also to deal with forces whose nature he cannot altogether comprehend; but he has been greatly aided in his efforts to control and utilise them by the foremost scientists of the present generation, who have devoted their lives to the elucidation of natural phenomena, and who have so far succeeded that the work of the practical electrician in taking advantage of their discoveries has been greatly facilitated. Some one has observed that it is useless to prophecy unless you know. We do not know what the future of electric lighting may be, and therefore we have no inclination to don the prophetic mantle; but we may safely assert that, if with the mechanism now employed to obtain and use the electric current the acme of perfection has been reached, the day is yet far distant when gas engineers need seriously concern themselves about the new competitor. Yet they are not to imagine that their business cannot be injured by unscrupulous speculators. Quacks are to be found in every industry, and the electric lighting industry is no exception to the rule. Such men go about from town to town, and even appear upon the platform before learned societies, and plausibly discuss the possibility of economically introducing electricity. By wilfully perverting facts, or purposely ignoring them, these men lend themselves to a fraud which ought to be denounced in the strongest language. The year that has gone has not been free from the influence of much of this quackery."

VIENNA.—The recent conflict between the Imperial and the municipal authorities of Vienna with regard to the scheme for a central electric lighting station which has been undertaken by the Continental Gas Association, has now been terminated by an acceptance of the proposals of the company. According to *Industries* there are at the present moment seven distinct stations for the supply of electricity projected for Vienna. These are the following:—1. A central station at Neubad for running 15,000 glow lamps in the shops and dwelling houses of the inner town; contractor, Herr Fischer. 2. A central station in Blutgasse, close to St. Stefan's Cathedral, also with 15,000 glow lamps distributed in various newspaper offices, shops, some private houses, and the Government printing offices; contractors, Messrs. Siemens and Halske. 3. A small central station close to the Union Hotel, where accumulators will be used, the number of lights not yet ascertained; contractor, Mr. de Calo. 4. Imperial Continental Gas Association, close to the new Burg Theatre, for 14,000 glow lamps, worked by steam engines and direct driven dynamos in conjunction with a series of accumulators; the light will be used in the two principal theatres, the Opera House, the Emperor's Palace, and the offices of the gas company; contractors, the Gas Company. 5. A small central station in the Paniglgasse, for a number of glow lamps distributed in the neighbourhood; contractors, Messrs. B. Egger and Co. 6. A central station in the suburb Mariahilf, for 12,000 glow lamps; steam power, 1,000 horse-power; there will be twelve dynamos, each giving 480 amperes and 125 volts; contractors, Messrs. Kremenezky, Engländer, and Leistler. 7. A central station at the water works in Nussdorf; number of lamps not yet ascertained; here transformers on the Zipernowsky system will be used. The conditions to which electric light contractors are, however, asked to submit are very onerous; for instance, the gas company are asked to pay a rental for the right of way for their street mains of 1kr. (about ·19 of a penny) per annum for every yard of conductor, and for every service lead between mains and houses 1fl. per annum. In addition, they are asked to hand over to the town 5 per cent. of their gross income from the sale of electricity. It is further proposed that, by giving a year's notice, the town can at any time compel the company to sell them the undertaking.

ELECTRIC LIGHTING AT THE COLONIAL AND INDIAN EXHIBITION.—The report of the Committee on Electric Lighting of the Colonial and Indian Exhibition has recently been issued in the form of a document marked "private and confidential," consisting of 12 folio pages, and containing much detailed information—including the amount of the fines incurred by certain of the contractors for various irregularities, which were mostly of a minor description. We are, however, enabled, without any breach of confidence, to subjoin a few details from certain portions of the report. It is already known that the firms who took part in the contracts were the following:—Messrs. Davey, Paxman and Co.; the Anglo-American Brush Company, Messrs. Crompton and Co., the Pilsen-Joel Company, the Electrical Power Storage Company, Messrs. Elwell-Parker and Co., and Messrs. Galloway and Sons. Mr. J. H. Cundall, and Mr. G. Schultz, were the electrical engineers appointed by the committee to superintend the operations. The general results are thus referred to:—"The Committee are glad to be able to report that no accident has occurred during the whole period of working, nor have there been any but trifling local interruptions of the light for brief periods. Moreover, there has not been even an alarm of fire in any one of the departments of the building." This statement will be admitted to be highly satisfactory, and to reflect the utmost credit upon all concerned. For the arc lighting altogether 28,300 yards of wire were used, and it is stated that the "average insulation on a fine dry day was 450,000 ohms, and on a wet day 300,000 ohms." For the incandescent leads 16,235 yards of wire were used, and the insula-

Digitized by Google

tion varied between 25,000 and 2,600 ohms. The report reads as if in each of the two cases the various circuits were joined up continuously, in order to measure the entire insulation resistance; but we do not know whether this was actually the case. In the illumination of the gardens 8,034 glow lamps were employed, and in the buildings themselves 1,851 lamps were hung, the average number in use being 1,667. These 1,667 lamps illuminated an area of about 106,447 square feet, and consumed 102,750 watts, being at the rate of about 0·9 watts per square foot. A large proportion of the lamps had already been used in the previous exhibitions, so that the record of their life is not very instructive. It is, however, satisfactory to note under these circumstances that the average life of lamps from the opening of the Exhibition (including all accidents) comes out as high as 1,200 hours. The majority of these lamps were either of the Edison-Swan or the Woodhouse and Rawson make, and there were also some Victorias and some of the old type Edisons. On the whole the technical portion of the report has been well drawn up, but in some parts it is difficult to obtain real information from it. For instance, in the appendices relating to the performance of the E.P.S. cells, it is necessary to undertake a careful collation of the various figures in the separate tables before the actual efficiency of the battery can be arrived at. We could have wished that the report had appeared at a somewhat earlier date, and also that it had not been considered necessary to treat much of it as "private and confidential," but it affords us much pleasure to recognise the valuable testimony which it bears to the very high standard of skill and efficiency which modern electrical engineering has in general attained.

THE VIEWS OF THE UNITED TELEPHONE COMPANY.—The *Pall Mall Gazette* publishes the following account of an interview between Mr. Brand, the chairman of the U. T. Company and a representative of that journal on the subject of the recent breakdown of the overhead wires:—"What view, Mr. Brand, has the Stock Exchange taken of the breakdown in your system?" "There has been a fall of ¾ to 1; but it shows how much we are progressing in public favour that when the storm of a year ago broke many of our wires our shares went down from 2 to 3. There is, however, no reason why there should even be a fractional fall. The cost of our repairs will certainly not exceed £5,000, while the drop on the Stock Exchange is equal to at least £60,000." "The complete dislocation of your system must, of course, have caused great inconvenience now that you have accustomed business men to its use?" "That is true, but the whole system did not break down. None of the cables gave way, and we had as many as 12,000 messages on the first day after the storm, and as we have spared no effort or expense to re-establish communications, that number was very speedily added to. We first of all directed our attention to making good the principal pole routes, as we term them, and after we had attended to the great highways, the mending of individual wires was proceeded with. We shall very shortly have our whole communications restored; and, considering the unfavourable weather and the shortness of the working day, that is not a bad result. Our trunk lines stood the strain admirably, although here and there poles bent or broke; but the weakness was as often as not in the roof, rather than in the lines and their supports." "Have you heard of any accidents in consequence of the breakage of wires?" "No, not a single accident. The storm has demonstrated that the dangers from overhead wires are merely imaginary. Of course, it is possible that there might be an accident, but the risk from a falling chimney-pot is much greater than from a broken wire. So far as I can learn, there is only one undoubted case on record, and that accident was caused, not by the wire while falling, but by its end being wound round a lamp-post by a passer-by, and an unlucky omnibus driver coming in contact with it, had his head knocked off, or something of that sort." "Is it possible for you to strengthen the overhead wires so that they may stand the strain better?" "We are doing what we can, but we have many obstacles to overcome. The way-leave is one of the greatest difficulties. The roofs are of varying heights, which causes unequal strains upon the wires, and as we cannot go where we please we have often to make long spans. If we had perfect freedom granted us by the Legislature we could lessen very materially the risk of a breakdown, and reassure the public on the score of safety. Our plan would be to increase the number of poles, lessen the span, and equalise their length. You will see at once that the wires would be much more stable then. I have every hope that the Legislature will increase our powers when public opinion is fully educated. The underground scheme is of course the great alternative, but to that there are both scientific and financial objections. An underground system would be very costly, and would necessitate a very large increase in the subscription, which would militate against the extension of the telephone. But that apart, it is questionable whether the telephone will work with the wire underground." "What is the extent of the telephone system in this country?" "That may best be gauged by giving you the number of instruments in use. The United have within the area of their patent licensed up to the close of last year between 100,000 and 120,000 instruments. That is a development which, while not so great as in America, is enormous. Mr. Raikes recently spoke of giving greater facilities to the telephone. I am not aware in what direction he proposes to do so, but if we are not handicapped in any way, there is no reason why we should not outstrip America."

THE WESTINGHOUSE COMPANY AND THE STANLEY ALTERNATING CURRENT DYNAMO.—It has already been announced that the Westinghouse Company of the United States have been engaged for some time past in making preparations for the introduction of the system of distribution by transformers, upon the most extensive scale. We understand that in addition to the Gaulard-Gibbs patents, the company has recently acquired the patent rights in several inventions relating to the use of alternating currents, both in this country and in the States. The validity of certain of the United States patents taken up by the company has, however, been challenged both by Brush and by Edison, and it is expected that protracted litigation will ensue, each of the parties being well provided with the sinews of war. The first step has already been taken by Edison, who commenced legal proceedings on the 24th ult. It is to be hoped that these disputes will not retard the development of a system which in many cases gives promise to effect a very considerable economy in central station lighting. The alternating current machine which the Westinghouse Company will employ has been designed by one of their own electricians, Mr. W. Stanley, assisted by Mr. Shallenberger, and others. The machine is said to have a remarkably large output; weight for weight the figures mentioned to us are as much as three or four times as good as those of modern low-tension continuous current machines of English make, while the selling price, it is said, will not exceed 30s. per horse-power for moderate sized machines. We hope shortly to give drawings and detailed description of this interesting machine, and in the meantime we take the following further particulars from the *Electrical Engineer* of New York:—"The body of the armature is cylindrical, 23in. in diameter and 12in. face, and is formed of discs of iron magnetically separated from each other, the con-

Digitized by Google

ducting wire being wound in flat coils upon its face. The field magnets, 16 in number, are arranged in a circle, with their poles facing inward toward the armature, and in close proximity thereto. The dynamo is driven at the rate of 1,080 revolutions per minute, thus giving 17,260 alternations of the current per minute, or 288 per second. The weight of the entire machine is about 7,000lb., and the total weight of copper wire on the armature and field-magnet about 800lb. The potential at the terminals of the dynamo when running is maintained at about 1,100 volts. An independent exciter is employed for the field, consisting of a small Stanley direct current dynamo of 150 volts and 10 amperes, driven at 1,800 revolutions per minute. The alternate dynamo and exciter are both belted to the shaft of an 18 by 16 Westinghouse automatic engine of 200 horse-power, and running at 276 revolutions." In the same journal appears a letter from Mr. Stanley, from which we make the following extract:—"While engaged in developing some of the 'modifications' of the Westinghouse system, I determined to design a constant E.M.F. dynamo of the alternating type, having from 16,000 to 20,000 reversals per minute. There seemed to be a general opinion that an alternating current dynamo with an iron-cored armature would result in failure, as the cores when subject to 16,000 reversals of polarity per minute would heat too greatly for practical use. It was found upon trial that the iron core instead of heating from self-induction, reduced the self-induction to a practical zero. That the great number of reversals per minute did not increase the magnetic lag; and that the calculations used in determining the electrical data of direct current machines were applicable to dynamos of the alternating type." From this extract it would almost appear that Mr. Stanley's machine belongs to that order of invention (of which we have had so many remarkable examples from the States) in which a high degree of practical success has been attained with a comparatively slender acquaintance with theory. We base this estimate on Mr. Stanley's use of the term "self-induction," a phenomenon which it would appear that he has confused with Foucault currents. We are quite ready to believe that an alternating machine can be built with iron in the armature, and it is, indeed, obvious that this is the only way in which an economical machine can be constructed, but we are at present somewhat sceptical as to the result being to reduce the self-induction of the armature "to a practical zero." We may remark, in conclusion, that it is too often taken for granted that self-induction is an unmitigated evil. It is true that self-induction, as a rule, restricts output, but it wastes no energy, and its presence may at times be positively advantageous.

The Post Office and the Recent Storm.—The *Pall Mall Gazette* publishes the following information obtained from the engineer-in-chief of the Post Office by a representative of that journal as to the effects of the recent snowstorm:—Of course there was a good deal of grumbling at the necessary delays, but on the 28th there were 3,776 messages handed in at the Stock Exchange which were sent over the ordinary wires. The following comparative figures certainly speak well for the energy of the department. They relate to the messages sent in the metropolitan district, through which the chief offices are connected with the central telegraph office by underground wires:—

	1885.	1886.
December 27 (Boxing Day)...	6,000	6,800
„ 28	9,700	9,900
„ 29	9,000	9,700

For the week the total messages numbered 670,000, and for the corresponding week last year 710,000; but, as the Bank Holiday did not fall in the same week last year, the difference is more than accounted for. For the week ended Saturday last the number of messages was 803,000, as compared with 736,000 last year, notwithstanding the fact that many wires were still stopped and that senders were warned that their messages would probably be delayed. The department has been able to have this good record while the wires were down by the free use of the Wheatstone instrument. Every means were used to get messages through, no matter how circuitous the route or involved the method. Some were sent on by train for part of the distance and then telegraphed, and others were first wired, then carried by train, and again wired. Some messages from Paris reached London *viâ* New York. The cost of repairs will be heavy, but it will not fall wholly on the Telegraph Department. All the wires along the railway lines are maintained by the respective railway companies, and the Post Office pays for maintenance an inclusive charge of £1 per mile per annum. They will therefore have to make good the wires on the lines. Those on the highways are, of course, maintained by the Post Office, and to repair and improve these where it is thought desirable something under £10,000 will probably be required. It may surprise some to learn that while Germany, which has been put so prominently forward, has 22,000 miles of underground wires, the English Post Office has a total length of full 20,000 miles. All the trunk lines are carried out of London underground, some to the distance of five miles from the Post Office, some ten, and some twenty, and they then emerge above ground. In every large town the same system is followed. We do not, of course, carry any of our wires under the high roads, as Germany presumably does; and from a military point of view, except in the contingency of a storm, there is no increased security by this method, for the route of underground wires could easily be discovered. It is the fact that Portsmouth, Plymouth, and Chatham were isolated for several days, and Aldershot for a single day, but had there been an emergency the first attention would have been given to these places, and the communications could have been rapidly restored. In certain possible contingencies it might be well to have underground communications with our naval and military stations, but the outlay would be a very heavy insurance premium indeed. The cost of an underground wire is £350 per mile, as compared with £35 overhead, while every additional wire costs £14 underground and £10 over. Beyond this, underground wires diminish the speed from 25 to 75 per cent. over long distances. By the multiplex system six messages are sent by one wire simultaneously when overhead, but in the case of an underground, for a distance of fifty miles, say to Brighton, scarcely two messages can be sent. Thus there is an enormous waste in the case of the underground to be added to the first cost, and, contrary to what is generally believed, the cost of maintenance, including renewal, is but little different to the cost of maintenance of overground wires. The telegraph authorities have given the subject their fullest consideration, and it is some time now since they mapped out the whole country and calculated the cost of a general underground system of wires to connect the principal towns in the United Kingdom together, and London with the landing places of the submarine cables. This could not be done for a less expenditure than £1,750,000 to £2,000,000, and, as the gross annual revenue of the department only amounts to the larger of these two sums, how to recoup itself for such an outlay becomes a difficult problem. If it were urged that we should at first, in view of political complications, only connect the Continent by underground wires, our great business towns would naturally claim the same privilege. No doubt the underground system will extend, as there is practically no room left on many roads, but its general adoption is yet in the far distance.

ELEMENTARY ELECTRICITY AND MAGNETISM.—II.

(Continued from page 211.)

Many motors have been constructed in which masses of iron are made to pass across the field of an electro-magnet, or number of electro-magnets, either with a reciprocating motion or with a continuous rotation, and by means of a "make-and-break" arrangement a current, from a battery or other source, passes round the coils of the electro-magnet, and excites them when the iron armatures are approaching the magnets, but the current does not flow while the pieces of iron are receding from the magnets, so that work is done on the iron while approaching a magnet, but its motion is unopposed as it recedes. In these motors, however, there is a great waste of power on account of the currents induced in the armatures, and the energy wasted in magnetising and demagnetising the field-magnets. They can only be employed when very small power is required and its expense is of no consequence. A similar remark applies to those motors in which one set of electro-magnets revolves in the neighbourhood of another set, the current in the revolving set being reversed at each half revolution so that the force acting upon it is always in the direction of its motion.

To obtain high efficiency in a motor the only conductor moving in the magnetic field should be the wire which conveys the currents, the magnetism of the field-magnets should be maintained constant, and in no case should a mass of iron be alternately magnetised and demagnetised, though there is little objection to this if the iron consists of thin discs insulated from each other and with their planes parallel to the lines of force in the field.

When a dynamo is employed to drive a motor it frequently happens that the dynamo is kept running continuously, but the motor is allowed to run only at intervals. It has been pointed out that to obtain high efficiency the resistance both of the dynamo and the motor must be kept very low. If the speed of the dynamo be kept constant the E.M.F. produced will remain nearly constant, and when the circuit is completed with the motor at rest, the current will be very great indeed, and either the engine will be stopped by the enormous load thrown upon it or the armature will be injured by excessive heating. To obviate this it is usual to introduce resistance coils of iron or German silver so adjusted that the whole E.M.F. of the dynamo cannot produce an injurious current through the whole series of coils. The coils are arranged so that they can be thrown out of circuit one by one by a suitable switch as the speed, and therefore the "back E.M.F.," of the motor, increases. When the motor is started the whole series of coils is introduced into the circuit. As the speed increases the switch is moved so as to throw out one coil after another, until all the resistances are thrown out, when the speed of the motor approaches that at which it is intended to be driven. The dynamo is kept running uniformly the whole time. To take a numerical example :—Suppose the dynamo running at 1,000 revolutions per minute to give an E M.F. of 120 volts, that the greatest current we wish to allow is 60 amperes, and that the resistance of the circuit, including the dynamo and motor, is $\frac{2}{3}$rds of an ohm. Then if the motors are stationary, the current, when it became steady, would be 180 amperes instead of 60 amperes. Self-induction, especially in the field-magnets of the motor, will prevent the current from instantaneously rising to this limit when the circuit is completed, but it would reach it in a short time if the motor were prevented from running. By introducing four resistance coils, each of $\frac{1}{3}$rd ohm resistance, the resistance of the whole circuit will be raised to two ohms, and the current reduced to 60 amperes. As the speed of the motor increases, its back E.M.F. will come into play, and when this has reached 20 volts, corresponding to a current of 50 amperes in the circuit, the switch may be moved forward so as to throw one of the coils out of the circuit. The resistance will then be $1\frac{2}{3}$rd ohms, and the resultant E.M.F. in the circuit 100 volts, so that the current will be again 60 amperes. As the speed increases the current will diminish, and when the current has fallen to 48 amperes the E M.F. will have fallen to 80 volts, or the back E.M F. of the motor will have reached 40 volts, and the switch may be moved forward so as to throw the next coil out of circuit. The resistance will then be $1\frac{1}{3}$rd obms, and the E.M.F. 80 volts, so that the current will again be 60 amperes. When the current has fallen to 45 amperes the back E.M.F. will have increased to 60 volts, and the next coil may then be thrown out. The last coil may be thrown out when the current has fallen to 40 amperes, for the back E.M.F. will then have reached 80 volts, and the resultant E.M.F. in the circuit will be 40 volts, which in a circuit of $\frac{2}{3}$rd ohm resistance will produce a current of 60 amperes. If the load upon the motor is so small that the speed increases beyond this the current will continue to diminish. If the load be uniform this must be the case, for if the speed has been attained with a current of 40 amperes it is clear that a current of 60 amperes will increase it, and therefore increase the back E.M.F. Suppose that the speed increases until the current has fallen to 45 amperes, and then remains steady. Since the resistance of the circuit is $\frac{2}{3}$rd ohm the resultant E.M.F. must be 30 volts, and the back E.M.F. of the motor 90 volts. The horse-power employed in driving the current against the resistance of the circuit—that is, in developing heat in the conductors, will be $\frac{30 \times 45}{746}$, or 1·81; that employed usefully in driving the motor will be $\frac{90 \times 45}{746}$, or 5·43, while the whole electrical horse-power developed in the dynamo will be the sum of these two quantities, that is $\frac{120 \times 45}{746}$, or 7·24, so that 75 per cent. of the electrical energy developed will be usefully employed in driving the motor. The engineer in charge of the motor might be provided with an ampere-meter, or current measurer, enabling him to observe the whole current in the circuit, and might switch out the resistance coils as above indicated, or he might have a volt-meter connected with the terminals of the motor armature, and therefore reading the back E.M.F. of the motor increased by a small quantity equivalent to the product of the current into the resistance of the armature. For each 20 volts indicated by the voltmeter the engineer should switch off one of the resistance coils.

Sometimes the E.M.F. of the dynamo is so great compared with that required to maintain in the circuit the maximum current permissible, that it would be dangerous to allow the circuit to be completed even for a few seconds when the motor is at rest without introducing extra resistance. In such a case an automatic cut-off should be provided. This is easily arranged by causing the current to pass through a small coil of wire, which, attracting a piece of iron, pulls over a lever and breaks the circuit as soon as the current exceeds a certain amount. The circuit can then only be again completed by the attendant. When the power of the engine employed to drive the dynamo is not much in excess of its rate of working when the system is running properly an additional safeguard to the electrical appliances is introduced, for if the primary current much exceed its proper limit the engine will be stopped. This may, however, be accompanied by the slipping or breaking of the belts, and ought to be avoided.

To render the variation of the current as small as possible the resistance coils should not all be equal, but that which is first thrown out should have the greatest resistance, and the resistance of the others should successively diminish, so that if r_1, r_2, r_3, r_4 represent the resistance of the coils, r_4 being that of the coil first thrown out of circuit, and if R denote the resistance of the rest of the circuit the five quan-tities,

$$R,\ R+r_1,\ R+r_1+r_2,\ R+r_1+r_2+r_3,\ R+r_1+r_2+r_3+r_4,$$

may form a geometrical progression.

Soon after Faraday's discovery of the induction of currents attempts were made to obtain currents of sufficient strength to be of practical value by the motion of a coil of wire in a magnetic field. When the field is sustained by a permanent steel magnet, the apparatus is called a magneto-electric machine. A simple form of this class of machine is that ordinarily used for medical purposes. It consists of a fixed horse-shoe magnet, before the poles of which two coils of wire are made

Digitized by Google

to revolve. These coils are furnished with iron cores which are connected at one end, so that the coils and iron form an arrangement precisely similar to an ordinary electro-magnet, only that the wire is much finer than that usually employed in winding electro-magnets. When the bobbins are exactly opposite the poles of the steel magnet, most of the lines of force of the magnet, instead of passing from pole to pole through the air, take the longer but less resisting path offered by the iron cores of the coils and their connecting piece, and thus pass through the middle of all the turns of wire in the coils. When the bobbins have been turned through a quarter of a revolution there will be no lines of force passing through them, and when they have been turned through half a revolution they will again be opposite the poles of the steel magnet; but their positions will be reversed. The lines of force will, therefore, pass in the opposite direction through the turns of wire. Throughout the whole of this half revolution, therefore, there will be a current flowing in the same direction in the coils, for the effect of diminishing the number of lines of force passing through in one direction is the same as that of increasing the number passing through in the other direction. As the bobbins pass the poles of the steel magnet the mumber of lines of force traversing them will be the greatest possible, and will for an instant be neither increasing nor diminishing, but as soon as the bobbins have passed the poles the current will begin to flow in the coils, but in the opposite direction. Hence, the direction of the current will be reversed at every half revolution, viz., when the bobbins pass the poles of the steel magnet. By placing a commutator upon the revolving shaft which carries the bobbins, the connections of the ends of the coils of wire with the external circuit may be reversed at the same instant as the currents in the coils, and the currents in the external circuit will then always be in the same direction.

The magnets of magneto-electric machines of this class are generally furnished with a sliding keeper. This is a bar of iron which can be brought in contact with the poles of the steel magnet, or can be removed to a considerable distance from the poles. Since this keeper is much shorter than the iron cores of the revolving bobbins with their connecting piece, it follows that when it is in contact with the poles of the magnet most of the lines of force will pass through it, and very few through the bobbins, even when they are opposite the poles of the magnet. Hence, the induction currents will be feeble. On causing the keeper to recede from the magnet a larger percentage of the lines of force will pass through the bobbins, and the induction currents will be correspondingly strengthened. When the machine is not in use the keeper should be placed in contact with the poles of the magnet, to prevent the loss of magnetism which is otherwise liable to take place. The ordinary magnéto-electric machine employed for medical purposes is a familar example of this class of machine (Clarke's).

The Siemens armature, as constructed in 1857, consists of a cylinder of soft iron, with two wide grooves cut in opposite sides. In these grooves wire is wound longitudinally so that the wire, except where it crosses the ends of the cylinder, is parallel to the axis of the cylinder. This armature is made to revolve in a cylindrical space which nearly fits it, and which is bored between two blocks of iron placed a short distance apart, and forming the pole-pieces of a horse-shoe magnet. As the armature revolves the lines of force pass from pole to pole of the magnet through the iron, and, therefore, through all the turns of wire wound on the armature. Hence, there will be currents induced in the coil of wire which will be reversed at every half revolution. In this machine a much greater number of lines of force can be made to pass through the coil than in the machine above described.

(To be continued.)

THE AMERICAN BELL TELEPHONE COMPANY.—During the year 1886 the American Bell Telephone Company supplied 42,306 sets of instruments, and had 19,916 returned, showing a net increase of 22,390. Last year, owing to exceptionally heavy returns, the net increase was only 4,153.

PRACTICAL DEDUCTIONS FROM THE FRANKLIN INSTITUTE TESTS OF DYNAMOS.*

BY CARL HERING.

(Concluded from page 170.)

The following assumptions were made, as the accurate data for deducing the same were wanting. The speed in the Edison No. 4 machine was not given in the report; that given here is the speed at which the makers say the machine is to be run, and it is assumed that the speed must have been very nearly this in the test. The percentage of the whole circumference of the armature which is embraced by the pole-pieces was, in the Weston machines, assumed to be about eighty per cent., as this was the proportion in some arc-light machines of the same makers, which we understand have the same type of frame. The distance between the pole-piece projections was determined from this in the Weston machines. In the Edison machines, the length of the pole-pieces and the armature-core was deduced from the statement in the report giving the length of useful wire in a coil; it was assumed that by the term "useful wire" was meant that which lies directly between the pole-pieces and the armature-core. In the Edison machines, it was assumed that the length of the armature-core was the same as that of the pole-pieces; in the Weston machines, this was the case.

As the electromotive force induced in an armature is dependent upon the amount of magnetism passed through per second, the first questions in designing armatures are: How great may the velocity of the moving wire be? What must its length be? What must the intensity of the field be? &c.

The first of these, the velocity of the moving wire—commonly called the "conductor or inductor velocity"—depends on the distance of the active wire from the centre of the shaft, and on the number of revolutions of the armature. It may be calculated from the speed and the mean of the external diameter and the diameter of the core. In the table (the table here referred to was given in *The Electrician* of Dec. 31, 1886, p. 170) the horizontal column *a* contains the external diameters, *b* the internal, and *c* the mean. From this mean value the circumference in feet was calculated, which, when multiplied by the speeds *d*, and reduced to seconds, gives the inductor velocities in feet per second, in column *e*. From these values, it is seen that the Edison armatures have a higher velocity of the moving wire; also, that it is preferable to obtain the high inductor velocity by making the diameter as great as practical, rather than to increase the number of revolutions, as will be seen by comparing the small, high-speed armature of the Edison No. 4 with the large one of the Nos. 10 and 20.

To obtain a constant by means of which the length of wire may be calculated, the total electromotive force in volts which was generated has been divided by the length of that part of the wire in which it is generated. This wire will be termed the "active wire," and, in these deductions, has been limited to that portion of the armature wire which lies directly between the pole-pieces and the armature-core. Strictly speaking this is not quite correct, as some induction does undoubtedly take place in some parts of the wire lying at the ends of the armature, and also in some of the longitudinal wires which are not directly between the armature-core and the pole-pieces; but the induction in both of these parts is presumably so small as compared to that in other parts that it may be neglected, especially as the constants are to be applied to similar armatures, thus eliminating this error. The length of the active wires was calculated from the following proportions:—Column *f* gives the number of coils or commutator-bars, *g* the number of turns per coil, and *h* the resulting total number of turns on the armature. The proportion of these coils which are active is calculated from the distance between the pole-piece projections, column *i* and the circumference determined from the diameters in column *a*; the ratio of this is given in column *j*, in percentage of the circumference of the armature which is active; this will also represent the percentage of the number of windings which is active. Column *k* gives the length of a pole-piece in inches, which is the same as the length of the armature-core. From

* From the *Journal* of the Franklin Institute for December.

Digitized by Google

these the total length of the active wire in feet can be calculated, remembering that every turn of wire on the armature represents twice the length of the pole-piece; but as the two valves of the armature-wires are in multiple arc, only half of this induces the whole electromotive force. The total electromotive force in volts, given in column *l*, is then divided by this half length of active wire in feet, giving the induction in volts per foot in column *m*. As this induction is slightly different in different positions of the wire with referenee to the pole-pieces, these results give the mean value. They show that the induction is considerably higher in the Edison than in the Weston machines; also, that it is very nearly the same in all the Edison, and nearly the same in the three Weston machines.

These constants are dependent on the velocity of the inductor, for it is evident that if the latter were higher the induction would be increased. In order, therefore, to properly compare these constants, it is necessary to eliminate the velocity by dividing these figures by the velocities in column *e*, thus giving the volts per foot which would be induced (in the respective fields) at a uniform velocity of one foot per second. This is given in column *n*, and shows the number of volts induced per foot for an inductor velocity of one foot per second. These may be compared with each other as the velocities are the same. They show that at the same velocity the induction is better in the Edison than in the Weston machines; also that the values agree very closely for all the Edison, except for the No. 4 machine, which may possibly be attributed to the number assumed for the speed, which was not taken in the test. For the Weston 6 M it is lowest, which is no doubt due to a less intense field.

The next question which naturally arises is, what was the intensity of the field in these machines? This may be determined as follows: We know that a volt is 100,000,000· times the unit of electromotive force in the absolute system, and also that one absolute unit of electromotive force is generated when a wire cuts lines of force at the rate of one per second; therefore, one volt is induced if a wire cuts 100,000,000· lines of force per second. As we know the number of volts in one foot (column *m*) in these machines, and also the number of feet moved through in one second (column *e*), we can readily calculate the intesity which the field must have had to induce that number of volts in one foot. To illustrate this, suppose the velocity was one foot per second, and that the induction was one volt per foot at this velocity, then it is evident that the surface moved over by one foot of wire in one second—that is, one square foot—must contain 100,000,000· lines of force; or, if the induction was two volts per foot, there must be 200,000,000. lines of force in this space, as this number must have been cut per second to generate two volts. Dividing this number by 144 will give the mean intensity of the field in number of lines of force per square inch. These figures are given in column *o*. They show that with one exception all the Edison machines have very nearly the same intensity of field; also, that it is somewhat lower in the Weston, especially in the 6 M machine; but, as will be seen, it is more economically obtained in this one, which indicates that it was probably not over saturated.

These values might also have been obtained by multiplying those in column *n* by 100,000,000· and dividing by 144, which is equivalent to multiplying them by 694,444. This will be seen by considering the principles of the deductions.

The total useful amount of magnetism in the whole field is evidently the intensity per square inch multiplied by the size of the field in square inches. As the intensity has been calculated from the amount of induction, the amount of magnetism thus obtained does not include the leakage of the magnetism—that is, those lines of force which are not cut by the armature wire; it therefore represents the useful magnetism only. The same lines of force which enter the armature at one pole-piece pass through it to the other pole-piece, and therefore the total number of lines of force is the intensity multiplied by the curved area of one pole piece. These figures are given in column *p*, and are deduced from columns *o*, *a*, *j* and *k*. The magnetism increases with the number of volt-amperes which the machine generates.

This amount of magnetism is generated at the expense of a certain quantity of electrical energy in the field-magnets. In order to get some approximate values for calculating roughly how much electrical energy will be required for generating in practice a certain amount of magnetism in similar fields, the figures in column *p* may be divided by the amount of energy in volt-amperes that was required in these cases to generate the respective fields. In the report the figures in column *q* are given, which are the energy in horse-power consumed in the fields. Unfortunately the resistance of the field without the regulator-box was measured only in one machine, so that the energy given here represents more than that used in the field-magnets themselves, thus introducing an error in all the deductions made from these values. It is presumed, however, that at full load the resistance in the box was not large, so that the error will probably be small. Reducing this energy in the field to volt-amperes, and dividing it into the amount of magnetism, gives the number of useful lines of force generated per volt-ampere in the field. These are given in column *r*. As they depend on so many different proportions of the parts of the field and magnet-coils, and also in a measure on the armature, they might vary considerably for different types of field-magnets, and can therefore be used only in making rough preliminary calculations. They agree tolerably well for these fields, except for the Weston 6 M, which is evidently better proportioned than the others. As these figures are the ratio of that which is produced to that which is required to produce it, they may be said to represent the *relative* efficiencies of the different fields, in which sense they represent no absolute efficiencies, but serve simply to compare the efficiencies with one another. In the Edison machines, we believe, wrought iron alone is used, while in the Weston both wrought and cast iron were formerly used together, and we presume were used in these machines also. Possibly the iron in the field of the Weston 6 M machine is not over saturated, which may be the reason of its high efficiency of field.

The wires of the armature being wound repeatedly around it, pass through the same field a number of times, thus utilising the same field in one revolution for successive inductions in the same wire. This number of turns, as given in column *h*, multiplied by column *j*, may therefore be said to represent the economic use of the field; it does not follow, however, that the best armature is the one having the greatest number of turns on it, as it is quite the reverse; other more important considerations, such as self-induction, sparking, &c., require that the number of turns of wire be as small as practicable.

In deducing the number of volts per foot, only the active wire was taken into consideration. In designing armatures it is therefore necessary to know what the proportion is between the active and the total length of the wire, for if the active length is determined first from the number of volts to be generated and the induction per foot, we must find what the total length is in order to determine the resistance or cross-section of the wire. This proportion of active to total length will evidently depend on several dimensions of an armature, and will therefore vary somewhat in different machines. For these machines it was determined as follows:—Column *s* contains the mean length of wire in one turn (where several smaller wires are in parallel they were considered as one); this multiplied by the number of coils in column *f* gives the total lengths in column *t*; these divided into the active length in column *u* give the percentage in column *v*. From the latter it will be seen that the economy of the wire is considerably better in the Edison than in the Weston, and that it is best in the Edison No. 20, the proportion between the length and diameter of the armature being greatest in this one. Most of the proportions from which these percentages have been deduced were given by the makers.

The density of the current in the armature wire can be determined from the diameters of the wire in column *w*, the number of wires in parallel in a coil in column *x*, and the total current in the armature in column *y*. Dividing the latter into the double area of cross-section of the wire in square mils., or the double sum of the cross-sections of the parallel wires, gives the number of square mils. per ampere in column *z*. These numbers vary somewhat with the current and with

Digitized by Google

several other proportions; they should therefore be used only as a general guide, or for making preliminary calculations. The best method for determining the cross-section is to find the resistance from the amount of energy which is allowed to be lost in the armature, which together with the total length of the wire as determined from the induction per foot, &c., gives the required cross section.

The percentage of energy in the armature as taken from the report is given in column *A*. Those in which the loss is least, Weston 6 WI and Edison No. 10, have the greatest area of cross-section of wire per ampere (column *z*), while the one in which the loss is greatest, Weston 7 M, has the least cross-section per ampere. This relation does not necessarily exist between them all, as the percentage of loss depends also on the induction per foot of wire, and therefore on the length of the wire.

The relative efficiencies of these armatures, as inductors, may be seen from the figures in column *C*. The efficiency as an inductor, apart from that as a converter of energy, is greater the larger the total amount of electrical energy induced (column *B*), and the less the amount of wire necessary to effect this induction; it may therefore be expressed by the quotient of the two. The figures in column *C* have therefore been calculated by dividing those in column *B* by the lengths in column *t* and by the double area of cross-section determined from columns *w* and *x*, the decimal point being changed to reduce them to a convenient form. By themselves these figures represent nothing, but by comparing them with one another they show which of the armatures are the best proportioned as inductors. They show that the Edison are considerably better proportioned than the Weston. The most efficient armature is, strange to say, the smallest one, Edison No. 4, which is no doubt due to its having the most intense field (column *o*), the highest speed (column *d*), and almost the smallest cross-section of wire per ampere (column *z*). This higher efficiency is, however, obtained at the expense of the efficiency of the field, as will be seen from column *r*. The useful commercial efficiency of the whole machine is therefore below the average, as seen from column *D*. Next to this armature, in point of efficiency as an inductor, is the largest one, Edison No. 20. Its high efficiency is no doubt due to the great intensity of field (column *o*), the very small amount of wire on the armature (column *t*), the relatively high inductor velocity (column *e*), the large proportion of active wire (column *r*), and the comparatively small cross-section of the wire, per ampere (column *z*). The field of this machine has next to the highest efficiency as seen in column *r*, and therefore, as might be inferred, the machine has the best useful commercial efficiency of all of those tested, as seen in column *D*. It may be interesting to mention here that in this machine which has the best efficiency, the armature wires cut the field less frequently than in any other, as seen from the number of turns in column *h*.

Another proportion which may serve as a guide in designing armatures, is the relation between the outside diameter of the armature and the diameter of the core, or what amounts to the same thing, the percentage of the external diameter which is taken up by the wire on both sides. These figures are given in column *F*, and are obtained by dividing twice the depth of the windings given in column *E* by the external diameter in column *a*. This is greatest in the smallest armature, Edison No. 4, showing another disadvantage of small armatures; it is least, and therefore best, in the Weston 6 M, which may partially account for the economic field shown in column *r*, as the latter depends on this non-magnetic space.

A few other proportions may be deducted from the data given. One of these is the proportion of the distance between the pole-piece projections and the distance between the pole-pieces and the armature core. This proportion should evidently be as great as practicable. The figures are given in column *G*, and are obtained from columns *i* and *E*, allowing about $\frac{1}{16}$ of an inch for clearance on each side. It is greatest for the largest machine, Edison No. 20, which may partially account for its economic field in column *r*. The reciprocals of one-half of the numbers in column *G* may be said to represent approximately the intensity of the leakage of magnetism, as compared to the intensity of the useful field at these places, as the lines of force have the choice of these two paths. But this will be only a rough approximation, as a field is always more intense at points or sharp edges.

Another useful proportion is the relation between the length and diameter of the armature core, as deduced from columns *k* and *b*. It is given in column *H*, which shows by comparison with column *v* the advantage of a long armature. The Weston machines appear to be uniform in this respect, the length being almost twice the diameter.

Column *I* gives the relation between the length and diameter of the bearings.

Column *J* gives the electromotive force between two neighbouring commutator-bars. If this is great enough to maintain an arc across the insulation of the commutator-bars (about twenty volts) there is danger of starting the well-known flash, encircling the whole commutator, if the brushes should be misplaced sufficiently far to start the arc. It will be seen to be far within the limit of twenty volts in all of these machines.

The Edison Nos. 10 and 20 machines afford a good opportunity to compare two armatures of different lengths, but having all the other sizes and proportions alike, including the number of windings, size of wire, depth of winding, &c., only that in the one three wires are connected in parallel, and in the other, two; and that in the No. 20 the distance between the pole-piece projections is greater, making a difference of about 10 per cent. in the number of active wires in favour of the smaller one. The chief gain of the long armature is seen in column *r*, in which it has the highest percentage, which partially accounts for the efficiency in column *C*, and the consequent commercial efficiency in column *D*.

The subject of self-induction of the armature was purposely omitted here, partly because insufficient data are given in the report to make any practical deductions regarding it, but principally because it is presumed that the self-induction in such armatures as these, with very few turns, is so small that it may be neglected in such rough values as have been deduced here. It is to be regretted that the resistance of the field-coils without the regulator-box was not measured in each case in order that the effect of the self-induction of the field-coils in increasing the apparent resistance could be calculated, and its relation to the number of pulsations or commutator-segments determined. In only one case was the field-resistance measured alone, and from this a calculation shows an increase of resistance of less than one-tenth of 1 per cent., and, therefore, probably less than the allowable error in measurement.

The fact that the Edison Nos. 5 and 20 machines gave way in the armature insulation will not lessen the value of these deductions to the designer of dynamos, as this was presumably a defect in the details of construction, and not in the proportion of parts.

The test of the Edison No. 20 machine was marked unofficial in the report because the preliminary run of ten hours was not on full load; but it is no doubt sufficiently accurate for the deductions of the approximate values of the table.

The deductions here made are not for the purpose of comparing the commercial value of these machines, as it has been shown in the tests that they are practically equal electrically. The most important consideration in this respect would be the cost of the machines and the cost of maintenance and attendance, which cannot be considered here.

For the benefit of any one not familiar with these machines, it may be added that they are all simple shunt machines, with cylinder armatures.

In conclusion, it may be said that the values deduced in the table may not be free from small errors, as great accuracy was not possible in all cases, owing to the want of some few detail dimensions; moreover, great accuracy has no particular value in such general deductions as these.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended January 14th amounted to £4,701.

THE ELECTRICIAN.

TO CORRESPONDENTS.

All communications to be addressed to 1, Salisbury-court, Fleet-street, E.C. Those relating to Subscriptions, Advertisements, back numbers of the Paper, and so forth, should be addressed to the Publisher; and those relating to Articles, Correspondence, or Notes, to the Editor.

All letters intended for insertion in THE ELECTRICIAN, *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

SUBSCRIPTIONS.

THE ELECTRICIAN *can be had, by order, from any newsagent, in town or country, at the various railway stations; or it can, if preferred, be supplied direct from the office, on the following terms (paid in advance):—*

	3 months. s. d.	6 months. s. d.	12 months. s. d.
For United Kingdom	4 11	9 9	19 6
,, Foreign Parts and Colonies:— Within Postal Union	5 6	11 0	22 0
,, Labuan, Persia, Aden, Mozambique, Zanzibar, India, China, Japan, Borneo, Java, Philippine Islands, & New Caledonia	6 1	12 1	24 2

Cheques and P.O. Orders to be made payable to C. H. W. BIGGS.

Advertisements intended for the current week's issue must be handed in not later than Thursday, 4 p.m.

VOLUME XVII.

Volume XVII. of "The Electrician," price 10s. 6d., is now ready.

Also cases for binding, price 2s.

1886.

II.—LAND TELEGRAPHS.

The telegraphic system being in the hands of the State, there is no record to be made of competition. The surprising increase of traffic which has been uninterruptedly going on since the adoption of the Sixpenny Tariff for inland telegrams is so regularly recorded in non-scientific newspapers that we need not reproduce the figures here. Suffice it to say that the result of this great reform has exceeded the most sanguine expectations, both as regards the number of messages dealt with and the revenue derived therefrom. The public on their part have not less reason to be satisfied with the manner in which this vast addition to the work of the Postal Telegraph Department has been performed. For a time there was considerable grumbling at the extra trouble imposed upon the senders of telegrams in regard to their addresses; but this was only for a time, and there has been a singular absence of complaint on the score of delay or diminished speed of transmission. If silence may be taken for content in this relation—and the public are not remarkable for patience or reticence where a State Department is concerned—we may infer that the heavy traffic under the new regulations, now approaching double what it was under the old, is disposed of as expeditiously and as correctly as was the comparatively light traffic when the shilling rate prevailed.

Improvements which have been made in the electrical appliances of the Department seem to justify the statement that this is actually the case. Increasing the number of wires would, of course, contribute to this end; and so complete were the preparations in this respect before the alteration of the tariff was effected, that no very considerable addition to the wire accommodation appears to have been required or made during the past year. To keep pace with the ever-increasing work, improvements in the apparatus have been relied upon; and these, it is needless to say, are the objects of unremitting attention at the hands of the departmental electricians. But for the scientific knowledge, mechanical ingenuity, and practical experience brought to bear upon its electrical appliances by the officers of this important department, under the supervision of Mr. W. H. Preece, the present requirements of the service probably would have to be met by a large augmentation of operators and wires. The improvements in the Wheatstone and Multiplex systems which we have seen at work in the Post Office, had they been devised and patented outside a Government department, might have made the fortunes of half a dozen private individuals, to say nothing of some entirely novel appliances which have been invented and perfected on the spot.
